# Chapter 1 - Basic Airway Management and Decision-Making

**Joseph E. Clinton** , **John W. McGill**

Airway management is widely preached as the first priority in the management of any seriously ill or injured patient. However, despite the lip service given to the importance of airway management, it is often overlooked and, consequently, can be a source of error in the care of the critically ill or injured patient. Although appropriate airway management is evident in all smoothly run resuscitations, inappropriate management often presages a cycle of patient deterioration and misguided therapeutic intervention.

Unfortunately, recognition of the need for airway management is only the first part of the problem in emergency resuscitation. Managing the airway may be one of the most difficult aspects of the entire resuscitation. Because of the sheer variety of airway difficulties possible, even the most skilled resuscitator can find the task challenging. Blood, loosened teeth, vomitus, swollen or distorted landmarks--all of these present formidable barriers to successful management. When obstruction occurs in conjunction with reflex clenching of the jaws and possible cervical spine injury, conventional airway management tools may be rendered useless. Time pressures imposed by the need to avoid cerebral anoxia force one to make difficult decisions concerning the use of risky maneuvers such as moving the neck, administering paralyzing agents, or using invasive procedures. Tools must be at hand, skills must be well practiced, and decision-making must be sharp if optimal emergency airway management is to occur.

Some solutions to the dilemmas faced in emergency airway management are presented in this and the following chapters. Minimally invasive approaches to airway establishment and emergency airway decision-making are described first in the current chapter with more advanced technique descriptions following in Chapters 2 through 4 . Decision algorithms are presented to help assemble the pieces of the airway management puzzle into a logical framework. Readers are encouraged to study the algorithms at their leisure to facilitate later decision-making when time is limited.

## DECISION-MAKING IN AIRWAY MANAGEMENT

The resuscitator must have many tools at hand to deal with the acutely compromised airway. Although proficiency may exist for all of the available maneuvers, the specific procedural choice often must be made in challenging circumstances. Rescuers should practice potential scenarios before facing actual airway management scenarios in the clinical situation. Failure to do so may lead to unnecessarily aggressive management in some situations or to irreversible hypoxic injury as a result of unnecessary hesitation in others.

Several parameters must be assessed quickly before an airway management choice can be made. The parameters to be considered are as follows:

1. Adequacy of current ventilation
2. Time of hypoxia
3. Patency of airway
4. Need for neuromuscular blockade (muscle tone, teeth clenching, severe obstructive pulmonary disease or asthma)
5. Cervical spine stability
6. Safety of technique and skill of operator

Consideration of these factors should guide a choice among those techniques described. This initial choice is often straightforward. Difficulty rises precipitously when the initial choice fails. Time becomes critical and safety of technique less important as the risk of irreversible hypoxic injury rises. Anxiety increases and error potential compounds under these circumstances. Forethought and practice are invaluable when making these decisions.

Schemata are offered in Figures 1-1 and 1-2 that outline the logic behind the airway choices. The first diagram (see Fig. 1-1) is the most complicated. It represents the choices among nonsurgical approaches to airway management that we have described. The end point of this diagram is either success or the decision to pursue surgical management. Note that time considerations may force a judgment in favor of surgical airway management when time is running out. The second diagram (see Fig. 1-2) is much simpler. Now that the decision to manage the airway surgically has been made, one need only choose among three available options. Consideration of patient condition, security of the airway approach, and invasive nature of the procedure are factors to be weighed in the final decision.

## ESTABLISHMENT OF AIRWAY PATENCY

The first concern in the management of a patient in critical condition is adequacy of the airway. Partial or complete airway obstruction must be overcome quickly. In some cases, such as an airway obstructed by a tongue, simple maneuvers will suffice. In other cases, particularly those in which myriads of obstructing agents are combining to block the airway, the task will be formidable. The tongue, dentures, swollen or distorted tissues, blood, and vomitus are common obstructing agents that make intubation difficult. Clearing obstructing agents may be made more difficult by muscular activity due to reflex stimulation or patient efforts to improve oxygenation. Moreover, the neck motion required for suction and intubation must be carefully managed in the face of potential cervical spine instability.

The wide availability of pulse oximetry monitors has greatly improved our ability to monitor oxygenation for patients at risk of airway or ventilatory compromise. [1] Clinically subtle deterioration is much more quickly and easily recognized using the monitors. They have become standard equipment in emergency departments, intensive care units, and operating rooms to allow early recognition of patient deterioration. Pulse oximetry is discussed in more detail in Chapter 6 .

**Airway Maneuvers**

Partial or complete airway obstruction resulting from *lax musculature* and *tongue occlusion* of the posterior pharynx may be overcome by a variety of maneuvers. The relative benefits of various airway-opening maneuvers have been examined. In a study of 120 anesthetized patients whose airways were obstructed by their tongues, Guildner compared the ease of performance of the neck-lift and head-tilt method, the jaw-thrust method, and the chin-lift method. He concluded that the chin lift was the easiest to perform and produced the greatest airway patency of the three methods tested. [2] Besides offering greater patency, the chin-lift method has the additional advantage that neck extension is unnecessary (Fig. 1-3 (Figure Not Available) , Tables 1-1 (Table Not Available) and 1-2) (Table Not Available) .

Partial airway obstruction in the patient with a decreased level of consciousness is commonly due to posterior displacement of the tongue. This may be recognized readily in the presence of snoring or stridor, but an apneic patient or one who is moving minimal air may not exhibit any audible evidence of airway obstruction. Some type of jaw-thrust or chin-lift maneuver should be performed on every unconscious patient to ensure airway patency. When uncertain about cervical spine status, the neck must be maintained in the neutral position. If the patient was found with a flexed or extended neck, the neck should first be restored to neutral position with gentle longitudinal traction. The chin-lift or jaw-thrust method is then performed. A combination of these maneuvers usually clears airways obstructed as a result of the position of the neck itself. The neck-lift and head-tilt maneuver, as described in cardiac life support courses, should not be used when cervical spine injury is suspected, because the extension of the spine produced during the maneuver endangers the spinal cord.

Clearing the airway of foreign material requires more than a simple jaw thrust. The occasional patient who presents with complete airway obstruction secondary to food aspiration may be treated with abdominal thrusts as described in basic cardiac life support. [3]

Partial or complete airway obstruction can be the result of upper airway hemorrhage, accumulation of the patient's own secretions, vomitus, or fractured dentition. When deciding on airway-clearing maneuvers, one must take these circumstances into account. Neck extension must be avoided or carefully minimized if the probability of a cervical spine injury is high. When stability of the spine is a concern, application of the abdominal thrust should be limited to the supine method described for unconscious victims. The abdominal thrust carries significant risks, compelling the rescuer to weigh the benefits of its application. [4]

**The Chin-Lift Maneuver**

The rescuer places the tips of the fingers, volar surface superiorly, beneath the patient's chin. The jaw is lifted gently forward. The patient's mouth is opened by drawing down on the lower lip with the thumb of the same hand. [2] Mouth-to-mouth resuscitation or other means of positive-pressure ventilation is provided if the patient is not ventilating

spontaneously.

**The Jaw-Thrust Maneuver**

The jaw-thrust maneuver is the second choice, again because neck extension is not necessary. Forward traction on the mandible is achieved by using two hands to grasp the mandibular rami and pull them forward.

**The Abdominal Thrust**

The abdominal thrust is a method to relieve a completely obstructed airway. The technique was popularized by Dr. Henry Heimlich and is commonly referred to as the *Heimlich maneuver*. The technique is most effective when a solid food bolus obstructs the larynx. Although a subject of controversy, a role for the maneuver has not been found for the resuscitation of near-drowning victims.

The conscious patient with an obstructed airway exhibits increased respiratory effort, anxiety, aphonia, and, occasionally, cyanosis. In the conscious patient, the maneuver is performed with the rescuer positioned behind the upright patient. The rescuer's arms are circled about the patient's midsection with the radial side of the clenched fist placed in the epigastrium of the patient. Care is exercised to position the fist midway between the umbilicus and the xiphoid of the patient. After proper positioning, the rescuer grasps the fist with the opposite hand and delivers an inward and upward thrust to the abdomen. A successful maneuver will cause the obstructing agent to be expelled from the patient's airway by the force of air exiting the lungs.

An unconscious, supine patient must be handled differently: the rescuer kneels next to the patient's pelvis facing cephalad. The palmar bases of the hands are placed in an overlapping fashion on the epigastrium at the same spot as that used in the upright patient. Inward, upward thrusts are delivered in this fashion with the same objective.

Abdominal thrusts are relatively contraindicated in pregnant patients and others with protuberant abdomens. A chest thrust similarly to that delivered in closed chest massage may be used instead. The upright patient may be delivered a chest thrust by placing the fist over the sternum. Experimental  primate models of infant airway obstruction show higher peak airway pressures with chest thrusts than with abdominal thrusts; a combined (simultaneous) chest and abdominal thrust produce even higher peak airway pressures. [6] Hence, a combined maneuver should be considered in the case of total airway obstruction that is unresponsive to simple abdominal thrusts.

Visceral injury can occur with the Heimlich maneuver. Excessive force may be responsible in such cases. In others, incorrect placement of the hands may play a role. Nonetheless, the technique can be life saving and should be used when needed. Attention to proper execution may limit complications.

# Positioning

Positioning the patient who has sustained multiple trauma can be a problem. Spinal injury and airway access priorities dictate that the patient should be kept in the supine position while immobilized on a backboard. Turning the patient on the side allows upper airway hemorrhage, secretions, and vomitus to drain externally rather than to collect in the patient's mouth, which can lead to aspiration and airway obstruction.

Guidelines for patient positioning must take into account the status of the patient's spine and the use of gravity to enable secretions to drain rather than accumulate in the airway. The following is a judicious approach to airway management in a patient *with spontaneous respiration*:

1. Initial airway maintenance accomplished by the chin-lift maneuver and the application of cervical stabilization (see Chapter 49) .
2. Immobilization of the patient on a spinal backboard.
3. With the position of the neck controlled, transportation of the patient on the side to facilitate airway drainage.

## Suctioning

Patient positioning and airway opening and clearing maneuvers are often inadequate to achieve the degree of airway patency desired. Ongoing hemorrhage, vomitus, and particulate debris often require suction to clear and maintain the respiratory passage. Three basic types of suctioning tips are available (Fig. 1-4) (Figure Not Available) . Each is suited to different types of airway obstruction problems.

*Dental tip* suction is most useful for clearing particulate debris from the upper airway. Vomitus is most readily cleared with this tip because it is least likely to become obstructed itself by particulate matter. The *tonsil tip (Yankauer)* suction device is used most effectively to clear upper airway hemorrhage and secretions. Its design is intended to prevent the obstruction of its tip by tissue and clot. The rounded tip is also less traumatic to soft tissues.

Unfortunately, the *catheter tip* suction device is the one most readily available in many hospitals. Often it is the only type of suction available. This device is inferior to the other catheter tips for suctioning before the patient has been intubated. After intubation, it works well for suctioning the trachea and bronchi through the tracheal tube. The dental tip device should be used during the resuscitation period and should be ready at the bedside. The dental tip allows rapid clearing of both particulate matter and hemorrhage, thereby expediting airway control.

Optimally, stabilization of the patient with multiple injuries will involve use of all three types of suction tips. The tonsil or dental tip should be attached to the suction source during the interval between patient evaluations because it is most likely to be the one needed on short notice. Both the tonsil tip and catheter tip should be stored next to the suction source so they can be attached when needed. It is essential that all physicians and nurses know the location of suction equipment and *know how to turn it on* during an

emergency. In the resuscitation rooms, the equipment should be connected and ready to operate and not kept in cabinets or wrapped in difficult-to-open packaging material (see Fig. 2-1) (Figure Not Available) . Interposition of a suction trap at the base of the dental tip suction device prevents clogging of the tubing with particulate debris. A trap that fits directly onto a tracheal tube has been described; use of this device allows effective suctioning during intubation (Fig. 1-5) (Figure Not Available) . [9]

Although no specific contraindications to airway suctioning exist, complications of incorrectly performed suctioning may be significant. Nasal suction is seldom required to improve oxygenation (except in infants), because most adult airway obstruction occurs in the mouth and oropharynx. Vigorous nasal suction can induce epistaxis and further complicate an already difficult situation. Suctioning that is prolonged may not be recognized during an emergency, but it should be avoided because it may lead to significant hypoxia, especially in children. *Suctioning should not exceed 15-second intervals*, and the provision of supplemental oxygen before and after suctioning should be routine (see also Chapter 5) . Basilar skull fractures can allow the inadvertent placement of nasal suction tubes in the brain (Fig. 1-6) (Figure Not Available) . Extreme care should be exercised when a basilar skull or facial fracture is suspected, because communication between nasal and intracranial cavities may exist.

Generally, it is best to perform suctioning *under direct visual inspection* or with the aid of the laryngoscope. Forcing a suction tip blindly into the posterior pharynx can injure tissue or convert a partial obstruction to a complete obstruction.

Complications may be avoided by anticipating problems and providing appropriate care during suctioning maneuvers. Epistaxis may be avoided by limiting the force applied during suctioning. Vasoconstrictor drops or spray, such as 0.25% phenylephrine, constrict the nasal mucosa and reduce the injury potential in patients who require repeated nasopharyngeal suctioning. The rescuer must be aware that the patient may develop transient pupillary dilation if the vasoconstrictor solution drips into the conjunctival space. [10] Naigow and Powasner found that suctioning induced hypoxia in dogs consistently and that it was best avoided by hyperventilating the animals before and after suctioning. [11]

## Artificial Airways

### Indications and Contraindications

Once the airway has been established through various maneuvers and suctioning, the patient may require further temporary support to maintain airway patency. The semiconscious patient who is breathing with an adequate rate and tidal volume at the time of the chin-lift maneuver may develop hypoxia because of recurrent obstruction if the maneuver is discontinued. Oxygen supplementation and an artificial airway may be all the support that is necessary. The use of an artificial airway also allows more efficient use of rescuer skills and relief from fatigue that is caused by the continuous application of chin-lift or jaw-thrust maneuvers.

Positive-pressure ventilation with a bag-valve-mask (BVM) device may be necessary to

bolster the patient's inadequate ventilatory effort or to provide total ventilation in cases of apnea. By maintaining airway patency, artificial airways facilitate spontaneous and bag-mask ventilation.

**Airway Placement Technique**

The simplest artificial airways are the oropharyngeal and nasopharyngeal airways (Fig. 1-7) (Figure Not Available) . Both are intended to prevent the tongue from obstructing the airway by falling back against the posterior pharyngeal wall. The oral airway may also prevent teeth clenching. The oropharyngeal airway may be inserted by either of two procedures. In the first procedure, the airway is inserted in an inverted position along the patient's hard palate. When it is well into the patient's mouth, the airway is rotated 180° and advanced to its final position along the patient's tongue, with the distal end of the airway lying in the hypopharynx. The second procedure involves the performance of a jaw-thrust maneuver, either manually or with a tongue blade, and the simple advancement of the airway into the mouth to its final position. No rotation is performed when the airway is placed in this manner. Once inserted, the oral airway may have to be taped in place to prevent expulsion by the patient's tongue.

The nasopharyngeal airway is placed by gently advancing the airway into a nostril, directing the tip along the floor of the nose toward the nasopharynx. When in final position, the flared external end of the airway should rest at the nasal orifice. Either of these two airways provides airway patency similar to that in a correctly performed chin-lift maneuver, but the nasal airway may be better tolerated by the semiconscious patient.

**Complications**

Few complications are encountered in the use of these airways. The oropharyngeal airway may cause obstruction if during its placement the tongue is pushed against the posterior pharyngeal wall. Care in placement will prevent this occurrence. In the patient whose reflexes are intact, the gag reflex may stimulate retching and emesis, and the semiconscious patient may not tolerate the oropharyngeal airway. If gagging is a persistent problem, the airway should be removed and a nasal airway or tracheal intubation should be considered. If the patient with airway compromise is comatose and lacks a gag reflex, the oropharyngeal airway *should not be used as a definitive airway*; tracheal intubation should be used instead. The oropharyngeal airway will keep the mouth partially open if an orogastric tube is placed for gastric lavage or suction, and it will prevent clenching of the teeth, which can obstruct an orotracheal tube.

The nasopharyngeal airway may offer an advantage over the oropharyngeal airway in that the nasopharyngeal airway is less likely to induce gagging. The same considerations that apply to nasal suctioning apply to placement of the nasopharyngeal airway. That is, care must be exercised not to induce epistaxis, and extreme caution is indicated in patients with a suspected basilar skull fracture or facial injury. All patients with oral or nasal pharyngeal airways should be observed constantly, because these devices are temporary measures and cannot substitute for tracheal intubation.

# BAG-VALVE-MASK VENTILATION

## Indications and Contraindications

Correctly performed, the BVM method of ventilation appears to be simple and effective. Still, it is fraught with difficulty and therefore deserves special mention. Bag-valve-mask ventilation should be used by experienced individuals who are able to ensure a tight mask seal in situations requiring positive-pressure ventilation. The BVM is often used with an oropharyngeal or nasopharyngeal airway in place. [3]

Inexperience is a relative contraindication to the use of a BVM. A rescuer who is not skilled with the BVM will achieve much better ventilation with mouth-to-mouth or mouth-to-mask breathing than with a BVM. However, concern regarding transmission of infectious diseases has reduced the willingness of the lay public and health professionals to perform mouth-to-mouth ventilations. [12] Although BVM ventilation may provide excellent respiratory support in the anesthetized, paralyzed patient in the operating room, the device frequently is of marginal value during cardiopulmonary resuscitation (CPR), during an ambulance run, or in the combative patient. A tight mask seal is mandatory to prevent loss of air volume during ventilation. Another hazard of BVM ventilation occurs when vomitus, blood, or other debris is present in the mouth or pharynx. The foreign material may be insufflated down the trachea if it is not cleared before ventilation. The three major problems encountered with BVM ventilation are inadequate tidal volumes, inadequate oxygen delivery, and gastric distention.

## Ventilation Technique

Achieving adequate tidal volume with BVM ventilation requires a tight mask seal and adequate compression of the bag. Even trained paramedics practicing on manikins have difficulty delivering tidal volumes above 650 mL, which is well below the 10-15 mL/kg recommended by the American Heart Association. A variety of mask configurations are available to facilitate a tight seal, but none substitutes for the practiced skill of the rescuer. For the single rescuer, only one hand can be used to achieve the seal because the other must squeeze the bag. The rescuer's hand must be large enough

to apply pressure anteriorly while simultaneously lifting the jaw forward. The thumb and index finger provide anterior pressure while the fifth and fourth fingers lift the jaw. Care must be exercised to deliver an adequate tidal volume by full compression of the bag. *Dentures generally should be left in place to help ensure a better seal with the mask.*

It has been suggested that effective BVM ventilation during CPR requires two hands and, therefore, two rescuers. [13] We suggest using the two-rescuer technique (Fig. 1-8 (Figure Not Available) *B*) whenever it is practical. The presence on the BVM device of a pop-off valve may further frustrate ventilation efforts in the patient with reduced compliance.

All BVM devices should be attached to a supplemental oxygen source (with a flow rate of 15 L/min) to avoid hypoxia. A significant problem with the BVM method is the low oxygen saturation achieved with various reservoirs. The amount of delivered oxygen is dependent on the ventilatory rate, the volumes delivered during each breath, the oxygen flow rate into the ventilating bag, the filling time for reservoir bags, and the type of reservoir used. The commonly used corrugated tube reservoir is the least effective of those examined by Campbell and colleagues. [14] It is too sensitive to ventilatory technique and does not alert the clinician to changes in oxygen flow. A 2.5-L bag reservoir and a demand valve are the preferred supplementation technique during BVM ventilation. [14]

Pediatric BVM devices should have a minimum volume of 450 mL. Pediatric and larger bags may be used for ventilation of infants with the proper mask size, but care should be taken to administer only the volume necessary to effectively ventilate the infant. Pop-off valves should be avoided because airway pressure under emergency conditions may often exceed the pressure of the valve. [3]

### Complications

Hypoventilation often occurs because of the difficulty of carrying out the technique properly. Three mechanisms can result in complications: poor mask seal, failure to achieve airway patency, and low tidal volume. Practiced skill development is necessary to avoid these errors. Gastric distention can also result from poor airway patency. Air is insufflated down the esophagus, which inflates the stomach. Consequently, the risk of regurgitation and aspiration increases. When assistance is available, the application of firm posterior pressure on the cricoid ring helps reduce gastric inflation during BVM ventilation. [15] [16] The technique must be used carefully in infants, whose airway is more pliable and subject to obstruction with excessive cricoid pressure. Even with proper BVM technique, aspiration can occur. The rescuer must be vigilant to recognize complications early and take corrective action.

## INTERMEDIATE AIRWAYS

*Intermediate airways* are those interventions that go beyond the maintenance of a patent airway. They represent a midpoint between airway establishment and true airway control. Airway control is secured by maneuvers such as tracheal intubation and tracheotomy, in which an endotracheal cuff isolates the trachea. The devices described in this section occlude the esophagus and allow ventilation across the larynx. The devices discussed are the esophageal obturator airway (EOA), the esophageal gastric tube airway (EGTA), the laryngeal mask airway (LMA) and the esophageal-tracheal Combitube (ETC) airway (Sheridan Catheter Corp., Argyle, NY). Two are designed to occlude only the esophagus (EOA and EGTA), one (LMA) seals the larynx at the hypopharynx level, and one ETC offers the versatility of use whether placed into the esophagus or the trachea. Each is designed for use in the unconscious patient who requires positive-pressure ventilation. The esophageal cuff or seal built into these devices reduces gastric content aspiration. The EOA and EGTA have fallen into general disfavor in recent years due to the gravity of errors in placement. Complications

including esophageal rupture and tracheal intubation have led many to prefer the ETC or LMA as an intermediate airway.

## Esophageal Obturator Airway and Esophageal Gastric Tube Airway

The EOA and the EGTA maintain airway patency in ways similar to the oral and nasal airways, but they also protect

the airway by occluding the esophagus to reduce gastric distention and regurgitation. The face mask permits use of these airways as positive-pressure ventilating devices. Air insufflated through the airway traverses the upper airway before crossing the larynx and entering the trachea. Ventilation from the EOA exits the airway through numerous ports in its hypopharyngeal portion (Fig. 1-9 (Figure Not Available) *A* and *B*). Ventilation from the EGTA is identical to mask ventilation, with the addition of esophageal occlusion. A port is available on the EGTA to vent the stomach. The attractiveness of the EOA and the EGTA for use in the apneic patient stems from their retention of much of the simplicity of the artificial airway with the addition of an important feature of more complicated airways--some protection against regurgitation and reduction of gastric distention.

### Indications and Contraindications

Speed and simplicity are advantages of the esophageal airway over tracheal intubation. Trained individuals can successfully place an esophageal airway in an average of 5 seconds, whereas the same individuals may need 20 seconds to perform a tracheal intubation. [17] [18] In one out-of-hospital study, failure to intubate was much higher with the endotracheal tube (19.4%) than with the EOA (1.7%). [19] Neck motion is not as necessary with the esophageal airway as it is with tracheal intubation. For these reasons, the EOA may be an effective adjunct in the management of the unconscious injured patient who requires respiratory assistance. Hypercarbia may occur more commonly with EOA ventilation as compared with endotracheal ventilation. [20] [21] The most difficult aspect of this form of ventilation is securing a tight fit with the mask. Dentures should be left in place to give support to the lips. Adequate tidal volume must be delivered to ventilate the lungs. [22]

There are various contraindications to the use of the EOA and the EGTA. Because the airway is not protected from pharyngeal secretions, the presence of active oropharyngeal bleeding and excessive secretions represent a relative contraindication to EOA and EGTA use. Because of attendant discomfort, the devices cannot be used in the awake patient. Size specifications preclude their use in the pediatric patient; 16 years is the age usually cited as the lower limit for EOA and EGTA use. The actual limiting factors are the size of the esophagus and the face; an adult-sized 14-year-old would certainly tolerate an EOA or EGTA if necessary. However, a small adult may not receive an appropriate fit. Other contraindications include esophageal injury or conditions predisposing to perforation. A patient who has ingested a caustic agent or one with a known esophageal stricture should not undergo esophageal intubation. As a precaution against pressure-related complications, it is recommended that the device not be left in place for longer than 2 hours. It must be recognized that the EOA and the

EGTA are *temporary* forms of airway control. This form of airway control is most often used in out-of-hospital care.

**Placement of EOA/EGTA**

The head is in the neutral position during placement of the EOA and the EGTA. Neck motion is unnecessary. The rescuer grasps and pulls the jaw forward. At this point, the rescuer inserts the assembled airway with the mask attached. The obturator tip is directed into the patient's posterior pharynx with gentle, steady pressure. The obturator is advanced down the esophagus until the mask rests flush against the face of the patient. Figure 1-9 (Figure Not Available) *A* illustrates the correct position at placement. The cuff should lie in the esophagus just distal to the carina of the trachea. The rescuer postpones inflation of the balloon until proper position is confirmed. The patient is ventilated with a tight mask seal on the face, and the lungs are auscultated. For effective ventilation, the mask seal must be tight. Breath sounds should be audible bilaterally. Unilateral breath sounds or failure of auscultation should lead the rescuer to reassess the airway placement. Pneumothorax or hemothorax may explain unilateral sounds, as may inadvertent main stem bronchus intubation. Tracheal intubation will result in the absence of breath sounds. The possibility of bronchial or tracheal intubation requires removal and replacement of the airway. Once satisfactorily placed, the esophageal balloon is inflated to 20 to 25 mL.

**Complications**

A 5% incidence of inadvertent tracheal intubation has been reported by Don Michael in experience with 29,000 placements. [18] In a subsequent smaller sample, a 2.9% (5 of 170) incidence was reported with a 100% mortality among the 5 patients. [23] One study comparing out-of-hospital EOA placement with endotracheal tube placement found that the occurrence rate for complications of the EOA that prevented resuscitation (tracheal placement, tube kinking) was nearly three times higher for the EOA (8.7% vs 2.6%). [24] If not quickly rectified, tracheal intubation with the EOA or tube kinking are disastrous complications that produce occlusion of the patient's airway. Disciplined examination for bilateral breath sounds is critical.

Esophageal lacerations of undetermined depth were found in 8.5% of autopsies of patients in whom the EOA was used. [19] Esophageal rupture has been found and reported in case histories. [25] [26] Since Scholl and Tsai first reported esophageal ruptures in 1977, [26] the recommended balloon inflation volume was reduced from 35 to 20 mL. No further ruptures or leakage around the cuff have been reported. However, factors other than balloon inflation volume that theoretically can contribute to rupture include careless balloon removal without deflation and forceful attempts at placement when obstruction is met.

*Tracheal intubation should be performed BEFORE removal of the EOA*, because vomiting often occurs following deflation of the balloon and EOA removal (see Chapter 2) . If the EOA cuff has been overinflated, it may partially occlude the trachea and make intubation difficult. In such cases, the balloon is partially deflated to facilitate tracheal

intubation.

## The Laryngeal-Mask Airway

The laryngeal-mask airway (LMA) (Intavent International SA, Henley-on-Thames, England) functions intermediately between an oropharyngeal airway and an endotracheal tube. It was developed for use in the operating room as an alternative for endotracheal intubation, but it has also been recommended for use in difficult intubations. [27] It consists of a tube fitted with an oval mask, rimmed with an inflatable cuff (Fig. 1-10 (Figure Not Available) *A*). Contrary to usual mask design, the mask is intended to reside in the hypopharynx rather than on the face. It is inserted digitally until its tip meets resistance in the upper esophageal sphincter. The cuff is then inflated, forming a seal around the glottic opening (see Fig. 1-10 (Figure Not Available) *B*). The result is a relatively secure airway. However, it cannot be considered to protect against gastric regurgitation. Leakage of the hypopharyngeal mask allows aspiration of emesis and gastric distention may occur with misplacement. Although the device may be used for prolonged periods under appropriate conditions, it is usually considered a temporary adjunct until tracheal intubation is established. [27]

### Indications and Contraindications

The LMA is indicated for patients requiring an airway who cannot be endotracheally intubated. The most frequently cited example is a patient whose anatomy prevents visualization of the larynx. Contraindications include the inability to open the patient's mouth and vomiting.

### Placement of LMA

The LMA is first checked for possible air leaks by inflating and deflating the cuff. If the patient has a gag reflex, deep oropharyngeal topical anesthesia or conscious sedation must be administered. With the patient's head in the sniffing position, the mask is lubricated and oriented so the mask opening is facing the tongue. With the index finger of the dominant hand placed on the proximal aspect of the mask, the mask is inserted into the mouth, firmly against the hard palate (see Fig. 1-10 (Figure Not Available) *C*). The index finger (or thumb) may also be used as a guide during advancement (see Fig. 1-10 (Figure Not Available) *D*). With one smooth motion, the mask is advanced until resistance is encountered. With the tip of the mask thus seated in the upper esophageal sphincter, the cuff is inflated. The lungs are auscultated to confirm correct placement.

While the sniffing position is desirable, it has been shown that LMA placement was 95% successful when the patient was placed in the neutral position with in-line immobilization, simulating a trauma setting. [28]

After successful placement of the LMA, several methods are available to achieve subsequent endotracheal intubation. The first method is simply to pass an appropriately sized endotracheal tube down through the lumen of the LMA, rotate the tube 90° so that the tip easily passes through the fenestrations, and advance it through the larynx to the

trachea (Fig. 1-11) (Figure Not Available) . This has been found to be successful in 90% of attempted cases. [29] The second method involves the use of a tracheal tube exchanger. The exchanger is passed blindly down the lumen of the LMA and into the trachea. The LMA is then removed and an endotracheal tube is passed over the tracheal tube exchanger. This method of tube placement must be combined with confirmation of exchanger location, because it has been shown to pass into the esophagus in up to 70% of attempts. [30] Confirmation of endotracheal tube location should be made (see Chapter 2) . The third and most dependable method of intubation with an LMA in place is via a fiberoptic scope. A lubricated, appropriately sized endotracheal tube is mounted over a fiberoptic scope, and this combination is advanced through the lumen of the LMA out through the mask and through the larynx. The scope is then removed, but the LMA may be left in place with the cuff deflated. If the LMA must be removed after a tracheal tube has been successfully placed through it, pass a tracheal tube exchanger down the tube, remove the tracheal tube/LMA combination, and replace it with a tracheal tube.

### Complications

Although the LMA works well in most cases, this airway has several significant drawbacks. Aspiration is always a possibility, because the cuff does not provide a watertight seal. Laryngospasm can occur if adequate anesthesia is not achieved. A significant air leak around the cuff may occur when high airway pressures exist, leading to poor ventilation. Finally, success rates in the operating room range from 94 to 98%; success rates in difficult emergency airway management are unknown, but they are undoubtedly lower.

### Conclusion

The LMA is a blindly placed intermediate airway that should be considered in patients who require establishment of an emergency airway but cannot receive endotracheal intubation. The technique is quick and simple, requires a minimum amount of training, and appears effective in the hands of paramedics, nurses, and respiratory therapists. [31] [32]

## The Esophageal-Tracheal Combitube

The ETC is a noninvasive airway device that is placed blindly. It allows for effective ventilation and oxygenation when placed in either the esophagus or the trachea. The device has two lumina running parallel to each other. One is perforated at the level of the pharynx and occluded at the distal end, similar to the EOA. The second lumen is open at the distal end, resembling an endotracheal tube. The device has two balloons: a proximal pharyngeal balloon that occludes the oropharynx by filling the space between the base of the tongue and the soft palate and a smaller, distal cuff that serves as a seal in either the esophagus or trachea (Fig. 1-12) (Figure Not Available) . [33] [34] The Combitube has compared favorably with the endotracheal tube with respect to ventilation and oxygenation in cardiac arrest situations. [35] [36] It is also placed more rapidly. [35]

**Indications and Contraindications**

The ETC is superior to other intermediate airways, because no face mask seal is necessary. It may be preferable to tracheal intubation in certain situations, because it can be placed blindly and is also effective in the esophageal or tracheal position. It is, therefore, more easily placed than an endotracheal tube and is indicated in situations in which tracheal intubation is difficult, neck motion is impossible, or the rescuers are not skilled in tracheal intubation.

The ETC should not be used in patients with an intact gag reflex and is not recommended in patients younger than 16 years or less than 5 feet in height. It is contraindicated in suspected caustic poisonings or proximal esophageal disorders.

**Placement of ETC**

The device is held in the dominant hand and gently placed caudally into the pharynx while the nondominant hand grasps the tongue and jaw between the thumb and index finger. The tube is passed blindly to a depth where the printed rings on the proximal end of the tube lie between the patient's teeth or alveolar ridge. The pharyngeal balloon is then filled with 100 mL of air, and the distal cuff is subsequently filled with 10 to 15 mL of air. The large pharyngeal balloon serves to both securely seat the ETC in the oropharynx and to create a closed system in the case of esophageal placement. Because approximately three-quarters of placements are esophageal, ventilation is begun through the longer (blue plastic) connector associated with the esophageal lumen. Chest rise and good breath sounds without gastric insufflation confirms effective placement in the esophagus. However, gastric insufflation without breath sounds and chest rise indicate a tracheal positioning of the tube and require changing the ventilation to the shorter (clear plastic) tracheal lumen. Auscultation of breath sounds over the lateral lung fields confirms endotracheal placement of the Combitube. If the tube is in the esophageal position, gastric suctioning can be accomplished by passing a catheter through the open lumen into the stomach while the patient is being ventilated via the other port.

An alternative method to identify position is to attach an aspirating device (see Chapter 2) to the tracheal or clear plastic shorter tube. The inability to easily aspirate air confirms esophageal placement necessitating ventilation via the longer blue esophageal tube. In the patient with ventilatory effort, $CO_2$ detector devices also may be useful.

A patient who has been successfully resuscitated with an ETC positioned in the esophagus should ultimately receive a definitive airway. The steps required to place a tracheal tube in this setting are detailed in Chapter 2 but consist generally of deflating the large pharyngeal balloon and, with the distal balloon still inflated, intubating around the ETC.

**Complications**

Inappropriate balloon inflation and incorrect ETC placement can lead to air leaks during ventilation. The most common placement error is an improper insertion angle. A more caudal, longitudinal direction is recommended, as opposed to an anteroposterior direction of insertion. Another caveat is that the ETC must be maintained in the true midline position during insertion to avoid blind pockets in the supraglottic area, which prevent passage of the tube. Attention to the ring markings on the tube at the level of the incisors ensures proper positioning of the tube. One must remember to first inflate the oropharyngeal balloon before inflating the distal balloon. Although unlikely, esophageal injury is theoretically possible with the overinflation of the distal balloon.

## SPECIAL CONSIDERATIONS

### Cardiac Arrest

Mouth-to-mouth and BVM ventilation may suffice for out-of-hospital care with short transport times or for the initial few minutes of ventilation in cardiac arrest. However, optimal BVM ventilation during CPR is impossible. Mouth-to-mouth and BVM ventilation are adequate and effective in the anesthetized or paralyzed patient with an empty stomach in the absence of chest compression, but they are *inadequate* for prolonged ventilation in the patient in cardiac arrest.

Proper BVM ventilation is probably harder to master than tracheal intubation, and prolonged attempts during CPR usually only distend the stomach and give the uninitiated a false sense of security. *Patients in cardiac arrest should be orotracheally intubated.* Most cardiopulmonary arrests are not associated with cervical spine injury. When there is suspicion of cervical injury, the following precautions should be followed.

### Potential Cervical Spine Injury

Any patient who has sustained a significant injury has the potential for cervical spine injury. Approximately 1.5 to 3.0% of initial survivors of all types of major trauma seen in emergency departments have significant cervical spine injury. [37] [38] It is interesting to note that this prevalence is not increased in the setting of significant head injury. Falls from heights and motor vehicle crashes are also common causes of spinal instability.

In patients with multiple injuries, the possibility of cervical spine injury warrants caution when considering tracheal intubation involving the use of the laryngoscope. It is prudent to provide adequate oxygenation while limiting neck extension until cervical spine injury is disproved. If the patient is severely hypoxic or apneic, immediate tracheal intubation may be necessary with in-line manual stabilization of the neck (without axial traction) by an assistant. When done cautiously, oral intubation of the unconscious spinal cord injured patient may be as safe as other techniques, including intubation with fiberoptic guidance. [39]

Note that mouth-to-mouth and BVM ventilation frequently require some degree of neck extension to open the airway. A cadaver study demonstrated increased neck motion

with BVM ventilation when compared to various intubation techniques, including oral intubation, lighted stylet guided oral intubation, and nasotracheal intubation. [40] BVM techniques may, therefore, be less desirable than the other methods of securing the airway and ventilating the patient.

Many institutions and some out-of-hospital systems use pharmacologic adjuncts, in-line cervical stabilization, and orotracheal intubation before cervical spine films are initiated. In the patient who is comatose, combative, or in severe respiratory distress without definite evidence of spinal cord injury, this approach is advocated, because it may be life saving. Precautions during intubation of the patient with known cervical spine fracture or its potential should include in-line stabilization of the cervical spine with attempts to minimize traction or lateral neck motion during the intubation procedure. Clinical experience is accumulating that supports the safety of this approach.

**Potential Epiglottitis/Supraglottitis**

Epiglottitis is often considered a disease of children between the ages of 2 and 8 years, but it is being recognized in adults with increasing frequency. [49] The typical presenting picture is that of an adult or child sitting upright, drooling, or spitting up oral secretions rather than swallowing. The voice may sound muffled. There is a history of a relatively abrupt onset of a sore throat that rapidly becomes more painful. Children commonly present with a high temperature, but adults usually are only mildly febrile. The disease is especially treacherous in children because of their small airways and their tendency to panic when an oral examination or insertion of an IV line is attempted.

Small children are most calm when allowed to sit on a parent's lap. An oxygen mask with oxygen flowing at 10 L/min can be held by the parent several centimeters from the child's face. If the child is using accessory muscles to breathe, every attempt should be made to keep the child calm. If a lateral radiograph of the neck taken on inspiration can be obtained without disturbing the child, it will often establish the diagnosis. On radiography, the inflamed epiglottis often appears thickened and rounded. The hypopharynx is dilated above the obstruction.

In cases of respiratory compromise, an epiglottitis protocol should be implemented rapidly. A preestablished protocol can save many minutes of time otherwise spent trying to reach all of the personnel needed to manage this critical emergency. When a child is suspected of having epiglottitis based on history and clinical presentation, the safest course of action to establish the airway should be pursued. The emergency physician should accompany the child at all times until the airway is secure and be prepared to intervene. Otolaryngologist notification should be included in the protocol because a tracheostomy may be necessary. [50] When operating room space or personnel are not available immediately, emergency department personnel must be prepared to manage the airway.

If the child lapses into a coma or stops making ventilatory efforts, the first step is to attempt to force oxygen past the obstruction by using mouth-to-mouth respiration or a BVM apparatus. Because the obstruction is edematous supraglottic tissue and epiglottis, positive-pressure ventilation often can displace the edema enough to allow

adequate ventilation. If this effort is unsuccessful, the emergency physician should attempt oral intubation. However, a normal larynx will not be visible because of the edema. The operator should attempt to pass an endotracheal tube through the slit-like opening that remains for the supraglottic airway. An assistant can compress the chest to force bubbles through the airway, as a means of locating the airway. [51] The assistant can also palpate the larynx and the trachea to detect the tube's entry into the trachea. If orotracheal intubation fails, the intubator should go directly to transtracheal needle ventilation (TTNV) (see Chapter 4) . The obstruction of epiglottitis is mainly inspiratory, so there should be no difficulty with chest hyperinflation with intermittent TTNV. This method should ease subsequent orotracheal intubation, because the path of the airway should be readily apparent as exhaled gases pass through it.

It is recommended that all children with acute epiglottitis receive tracheal intubation. [52] If the child is not in distress, an IV line can be established before intubation for appropriate drug administration, although some operators prefer to delay IV placement until after inhalation anesthesia.

Adults and cooperative older children with suspected epiglottitis can be examined directly. It is good practice to visualize the epiglottis and the vocal cords of the stable older patient with laryngeal tenderness who is complaining of a severe sore throat or difficulty swallowing. A mirror, fiberoptic scope, or a right-angle scope can be used to do this (see Chapter 68) . In epiglottitis, the pharynx and tonsils usually do not appear inflamed, a finding that might otherwise explain the symptoms. Adults with epiglottitis do not always

need to be intubated if rigorous monitoring can be accomplished, a skilled intubator is immediately available, and the patient is not in distress. [49] Orotracheal intubation for epiglottitis is not as difficult in adults as it is in small children. Transtracheal needle ventilation can also be used in adults who are difficult to intubate.

**Jaw Clenching**

Hypertonus induced by neurologic dysfunction is a common complicating factor of airway management, especially in the patient with multiple injuries, drug overdose, or seizures. Jaw clenching may be a lethal complication when it prevents clearing of blood, vomitus, or foreign bodies in the airway. No more difficult airway problem exists than occlusion of the nasal and oral passages by vomitus while the patient's teeth are tightly clenched. Respiratory efforts may lead to severe aspiration, and although the hypertonus gradually gives way as the brainstem becomes progressively hypoxic, the cerebrocortical hypoxic insult sustained in the process may be irreversible. Various disease states can lead to a similar scenario in which the jaws are clenched in the presence of upper airway hemorrhage or the accumulation of secretions.

Jaw clenching and cervical spine injury can, of course, occur together. At times, the blind nasotracheal route of intubation may be adequate for airway management while minimizing the risk of further spine injury. However, at least a small degree of spontaneous air movement should be present for the blind nasotracheal approach to be successful. Although a serendipitous success may occur in the apneic patient, it is

recommended that time not be wasted on this approach in the completely apneic patient.

Neuromuscular blocking agents are generally an effective means to overcome jaw clenching in the breathing patient. Both neuromuscular depolarizing and nondepolarizing agents may be administered IV to induce paralysis and allow orotracheal intubation. Neuromuscular blocking agents and their administration for intubation are discussed in Chapter 3 .

**Apnea with Airway Obstruction**

Despite the many nonsurgical approaches to tracheal intubation discussed in this chapter, the patient who is apneic secondary to deep airway obstruction may be served best by a surgical airway. When maneuvers to relieve airway obstruction are unsuccessful and direct laryngoscopy is not possible or cannot rapidly alleviate the obstruction and permit ventilation, the operator should rapidly move to a surgical airway approach (see Chapter 4) .

## CONCLUSION

Airway management is the most fundamental aspect of emergency care. Every rescuer must know basic airway maneuvers and be able to use them instinctively. When basic maneuvers fail, airway management rapidly becomes more complex. Familiarity with the ingenious intermediate airway devices can often reverse a deteriorating situation and provide the rescuer with a temporary solution to an airway dilemma. When basic and intermediate maneuvers fail, complexity, risk, and exigency mount. Choices become more critical and complications more likely. Advance consideration of situations represented in the airway management algorithms is a wise practice for the emergency physician. It may hasten accurate decision-making when time becomes critical. In this chapter we have described basic and intermediate airway techniques and offered a logical schema for their use in the patient with an acutely compromised airway. Subsequent chapters deal with the more advanced airway techniques of tracheal intubation and cricothyrotomy.

# Chapter 2 - Tracheal Intubation

**John W. McGill** , **Joseph E. Clinton**

Tracheal intubation is generally considered the most definitive means of airway control. As discussed in Chapter 1 , the decision to tracheally intubate must consider the patient's physiologic status, anticipated patient care needs, operator experience, and features related to preparation for the procedure. This chapter discusses the indications for tracheal intubation in greater detail as well as the preparation for intubation and the key steps and modifications of the actual procedure. Chapter 3 discusses the pharmacologic adjuncts (including pharmacologic paralyzing agents) for facilitating tracheal intubation and their administration. Chapter 4 discusses more invasive means of establishing an airway and ventilating the patient. The general decision-making that is relevant to these techniques has been presented in Chapter 1 and should be reviewed prior to proceeding with this chapter.

## GENERAL PREPARATION

Preparation is the key to successful airway management. Two general areas of preparation should be addressed before undertaking the first attempt at definitive airway management in a clinical setting. The first is mental and physical preparedness. The second is the assembly of essential intubation equipment.

Mental and physical preparation comes from reading about the procedures, discussing the principles and details with instructors, practicing the techniques on intubation mannequins or in the animal laboratory, and finally performing the technique under supervision in a controlled clinical setting. Studies addressing various approaches to tracheal intubation are generally performed under optimal conditions (i.e., with equipment available and appropriate preparatory training). Also, often hidden within the study findings are individual learning curves. Therefore, it is overly optimistic to expect to match the success reported in the literature when first attempting a new intubation technique. However, the goal of preparation is to be as high on the learning curve as possible prior to the first clinical application of a new intubation technique. Further, continued rehearsal and application of the techniques that have been learned are important for skill maintenance.

Each approach to tracheal intubation has a preferred training format. Orotracheal intubation, for example, may be simulated with a mannequin, whereas retrograde intubation is best learned using an animal or cadaver model. Orotracheal intubation is likely to be successful on the first attempt, whereas considerable practice is required for facile use of the scope for fiberoptic intubation. In preparation for managing critical airway problems, maximal hands-on training is desirable.

The second general area of preparation is material preparedness (i.e., the immediate availability of all essential equipment required to optimally perform the airway maneuvers that are within the capabilities of the care provider). This may be accomplished by the wall-mounting of essential resuscitation equipment. [1] Alternatively,

dedicated adult and pediatric airway carts may be used for placement of the equipment in an open, organized, and labeled manner that can be regularly checked (Fig. 2-1) (Figure Not Available) . [2] The worst moment to realize that a vital piece of equipment is missing is when a patient's life depends on it. The importance of this concept cannot be overstated. *Technical expertise cannot substitute for the lack of essential equipment.*

In airway management, failure has ominous consequences. Mental, physical, and material preparation maximizes the chances of success.

## AIRWAY ANATOMY

Requisite for a discussion of procedures in airway management is a common understanding of airway anatomy and its terminology (Fig. 2-2 *A* and *B*). The following terms are used frequently in this chapter:

*Arytenoid cartilages*

> the paired cartilages forming the posterior aspect of the laryngeal inlet nasal cavity, from the external nares to the choana.

*Nasopharynx*

> from the end of the nasal cavity (choana) to the level of the soft palate.

*Oropharynx*

> soft palate to the upper border of the epiglottis.

*Hypopharynx (laryngopharynx)*

> epiglottis to the lower border of the cricoid cartilage.

*Vallecula*

> the space at the base of the tongue formed posteriorly by the epiglottis and anteriorly by the anterior pharyngeal wall.

*Laryngeal inlet*

> the opening to the larynx bounded anterosuperiorly by the epiglottis, laterally by the aryepiglottic folds, and posteriorly by the arytenoid cartilages.

*Piriform fossae (recesses)*

> the pockets on both sides of the laryngeal inlet separated from the larynx by the

aryepiglottic folds.

*Corniculate cartilage*

the posteromedial portion of the arytenoid cartilage.

*Cuneiform cartilage*

the anterolateral prominence of the arytenoid cartilage.

*Glottis*

the vocal apparatus, including the true and false cords and the glottic opening.

*Glottic opening (rima glottidis)*

the opening into the trachea as seen from above through the vocal cords.

## OROTRACHEAL INTUBATION

### Indications and Contraindications

Any clinical situation in which a definitive airway is necessary and limited neck motion is permissible is an indication for orotracheal intubation. Many of these situations, including cardiac arrest, airway compromise in infection and trauma, and airway obstruction are discussed in detail in Chapter 1 . Most orotracheal intubations are accomplished using a direct laryngoscope. An unstable cervical spine injury is a relative contraindication to direct laryngoscopy.

### Equipment

#### Laryngoscope

Facility in the use of the direct laryngoscope is a prerequisite for orotracheal intubation. Various adult and pediatric blade sizes are available. There are two basic blade designs-- curved (MacIntosh) and straight (Miller and Wisconsin). Slight variations in laryngoscopic technique follow from one's choice of blade design, which is often a matter of personal preference. The tip of the straight blade goes under the epiglottis and lifts it directly, whereas the curved blade fits into the vallecula and indirectly lifts the epiglottis via the hyoepiglottic ligament to expose the larynx. Special blades designed for the anterior larynx include the Siker and the Belscope (Avulunga Pty Ltd, New South Wales, Australia).

Each blade type has advantages and disadvantages. The straight blade is usually a better choice in pediatric patients, in patients with an anterior larynx or a long floppy

epiglottis, and in individuals whose larynx is fixed by scar tissue. It is less effective, however, in patients with prominent upper teeth, and it is more likely to break teeth. Use of the straight blade is also more often associated with laryngospasm due to its stimulation of the superior laryngeal nerve, which innervates the undersurface of the epiglottis. A straight blade may inadvertently be advanced into the esophagus and initially present one with unfamiliar anatomy until it is withdrawn. The blade has a light bulb at the tip that may slightly hamper vision. The wider, curved blades are helpful in keeping the tongue retracted from the field of vision, allowing for more room in passing the tube in the oropharynx, and they are generally preferred in uncomplicated adult intubations. Aside from patient considerations, some clinicians prefer the curved blade because they find it requires less forearm strength than the straight blade.

**Tracheal Tubes**

The standard endotracheal tube is plastic and measures approximately 30 cm. Tube sizing is based on internal diameter (ID), measured in millimeters, and ranges from a 2.0 to a 20.0 mm tube, increasing in increments of 0.5 mm. The outer tube diameter is 2 and 4 mm larger than the internal diameter. [3] Tube size is printed on the tube. There is also a scale, in centimeters, for determining the distance along the tube from the tip.

Adult men will generally accept a 7.5 to 9.0 mm orotracheal tube, whereas women can usually be intubated with a 7.0 to 8.0 mm tube. In most circumstances, tubes smaller than these should not be used, especially in patients with chronic obstructive lung disease who may be difficult to wean from the respirator due to excessive airway resistance from a small tube. However, in emergency intubations, particularly if a difficult intubation is anticipated, many clinicians

choose a smaller tube and change to a larger tube later if necessary. One exception is in the burn patient, in whom one places as large a tube as possible on the initial attempt because swelling may prohibit subsequent tube placement. For nasal intubation, a slightly smaller tube (by 0.5 to 1.0 mm) is chosen.

The cuff of a standard tracheal tube is high-volume and low-pressure. A clinical test for determining correct cuff inflation is to slowly inject air until no air leak is audible while the patient is receiving bag-tube ventilation. This usually occurs with 5 to 8 mL of air if the proper-sized tracheal tube has been selected. Many clinicians use the tension of the pilot balloon as a guide to cuff inflation; slight compressibility with gentle external pressure indicates adequate inflation for most clinical situations. For long-term use, cuff pressure should be measured and maintained at 20 to 25 mm Hg. Capillary blood flow is compromised in the tracheal mucosa when the cuff pressure exceeds 30 mm Hg.

In *infants and children*, the following formula is a highly accurate method for determining correct tracheal tube size:

Tube size = [4 + age (years)]/4

For most clinical situations, however, using the width of the nail of the little finger as a

guide is sufficiently accurate and has been shown to be more precise than finger diameter 45911 (Fig. 2-3) . [4]

Correct tube size is especially important in the pediatric population (Table 2-1) (Table Not Available) , because most patients younger than 8 years are intubated with an uncuffed tube; adequate tube size is necessary to provide a good seal between the tube and the upper trachea and to prevent aspiration. A cuffed tube is used in children with decreased lung compliance who may require prolonged mechanical ventilation. In a child, the smallest airway diameter is at the cricoid ring rather than at the vocal cords, as in adults. Hence, a tube may pass the cords but go no farther. Should this occur, the next smaller sized tube should be passed after reoxygenation.

Adult endotracheal tubes will accept a standard adaptor on which the ventilator tubing will fit. Pediatric tubes require a special adaptor with a distal end small enough to accommodate the small tube size.

**Preparing for Intubation**

Before beginning intubation, a number of issues should be addressed. In chronologic order, they are (1) confirm that
the required intubation equipment is available and functioning; (2) position the patient correctly; (3) assess the patient for difficult airway; (4) establish intravenous (IV) access, time permitting; (5) draw up essential drugs, and; (6) attach the necessary monitoring devices. In the haste of the moment, it is a common error to fail to position the patient properly or to proceed with the procedure before the proper equipment is assembled and checked. Simple omissions, such as failing to restrain the patient's hands, removing dentures, or misplacing the suction device, can seriously hamper the performance of the procedure. A suggested pre-intubation checklist is presented in Table 2-2 .

In addition to the preparation necessary for optimum patient care, the operator should also minimize exposure to potentially infectious materials (see Chapter 75) . Generally, the operator should be gloved and should wear eye and mouth protection to guard against exposure to patient secretions.

The endotracheal tube cuff should be checked for leaks by inflating the balloon before attempting intubation. The tube is prepared for placement by passing a flexible stylet down the tube to increase its stiffness and enhance control of the tip of the tube. The stylet should not extend beyond the end of the tube. The tube is then bent in a gradual curve with a more acute angling in the distal one-third to more easily access the anterior larynx. The tip and cuff of the tube are lubricated with viscous lidocaine or another water-soluble gel.

The patient should be positioned to optimally align the oral, pharyngeal, and laryngeal axes (Fig. 2-4) . The desired position was aptly described by Magill to make the patient appear to be "sniffing the morning air," with the head extended on the neck and the neck *slightly flexed* relative to the torso. A small towel under the occiput (to raise it 7 to 10 cm) may facilitate positioning. Positioning of the head and neck is a critical step;

nonoptimal head positioning may be the sole reason for some intubation failures.

| | TABLE 2-2 -- Suggested Preintubation Checklist |
|---|---|
| 1. | An assistant should be in the room watching the cardiac monitor, blood pressure, and $O_2$ saturation while observing the patient for signs of decompensation. The assistant should be instructed to inform the operator if more than 30 sec have elapsed without ventilation. |
| 2. | An IV infusion should be running properly. Oxygen should be administered to the patient. |
| 3. | Draw the necessary drugs (e.g., atropine, lidocaine, paralyzing agent, induction agent). |
| 4. | Attach the bag-valve-mask to an oxygen source (rate of 15 L/min). |
| 5. | If used, a stylet should be inserted properly into the tracheal tube. |
| 6. | Check the integrity of the balloon on the tracheal tube. |
| 7. | Have tape or commercial tube stabilizer available. |
| 8. | Check laryngoscope light source. Have a second light source, a selection of blades, and additional endotracheal tubes available. |
| 9. | Turn on the oral suction device and place the suction tip under the mattress to the left of the patient's head. Prepare the catheter suction for postintubation use. |

| 10. | Place the syringe to inflate the endotracheal tube balloon on the stretcher to the right of the patient's head. An option is to attach a syringe to the pilot balloon of the endotracheal tube. |
|---|---|
| 11. | If the patient is awake, restrain the hands. |
| 12. | Remove the patient's dentures (delay this action until immediately before intubation if patient is being bag-mask ventilated). |
| 13. | Check the cardiac monitor leads and the rhythm strip immediately before the intubation attempt. |
| 14. | Check for optimal head positioning: neck slightly flexed and head extended on the neck (conditions permitting). May be facilitated by placing a towel under the patient's occiput to raise it 10 cm. |
| 15. | Have an aspiration device for esophageal detection or an end-tidal $CO_2$ detector at the bedside. |
| 16. | Radiology department should be alerted for the postintubation chest radiograph. |

**The Difficult Airway**

The majority of difficult intubations are predictable. Perhaps the most frequently encountered condition associated with a difficult intubation is the agitated or combative patient. Fortunately, this condition can be readily eliminated through pharmacologic intervention (see Chapter 3) . The classic parameters that predict a difficult intubation include a history of previous difficult intubation, prominent upper incisors, limited ability to extend at the atlanto-occipital joint, [5] poor visibility of pharyngeal structures when the patient extends the tongue (Mallampati's classification, or the tongue/pharyngeal ratio) (Fig. 2-5 A), [6] limited ability to open the mouth, [7] a limited direct laryngoscopic view of the laryngeal inlet, [7] and a short distance from the thyroid notch to the chin with the neck in extension (Fig. 2-5 B). [8] Radiographic indicators of the ease of intubation include the mandibular length-to-height ratio [9] and the distance from the spine of the atlas to the occiput. [10] In emergency airway management, many of these predictors are

not obtainable. An extensive history is rarely available, the patients are frequently uncooperative, and the presence of trauma limits movement of the neck. Fortunately, some of the key predictors are apparent simply by observing the external appearance of the patient's head and neck.

Patients with neck tumors, thermal or chemical burns, traumatic injuries to the face and anterior neck, angioedema and infection of the pharyngeal and laryngeal soft tissues, or previous operations in or around the airway suggest a difficult intubation because distorted anatomy or secretions may compromise visualization of the vocal cords. Facial or skull fractures may further limit airway options by precluding nasotracheal intubation. Patients with ankylosing arthritis or developmental abnormalities, such as a hypoplastic mandible or the large tongue of Down's syndrome, are difficult to intubate because neck rigidity and problems of tongue displacement can obscure visualization of the glottis.

Besides these obvious congenital and pathologic conditions, the short, thick neck poses the greatest difficulty for performing orotracheal intubation. In such individuals, the larynx is anatomically higher and more anterior, which makes it harder to visualize the vocal cords. These individuals are easily identified by observing the head and neck in profile. In such patients, apply laryngeal pressure and consider using the straight blade. Use of other options, including nasotracheal intubation, may be required.

It should be emphasized that some patients, despite normal-appearing anatomy and the absence of a complicating history, are unexpectedly difficult to intubate. One must be prepared for this rare but inevitable occurrence.

## Procedure

### Adults

**Direct laryngoscopy.**

The operator is stationed at the patient's head (Fig. 2-6) . The patient is generally supine with the head at the level of the operator's lower sternum. To maintain the best mechanical advantage, the operator keeps his or her back straight and does not hunch over the patient; any bending should occur in the knees. The left elbow is kept relatively close to the body and flexed to provide better support. In the severely dyspneic patient who cannot tolerate lying down, direct laryngoscopy can be performed with the patient seated semi-erect and the laryngoscopist on a stepstool behind the patient. [11]

The laryngoscope is grasped in the *left* hand with the blade directed toward the patient from the hypothenar aspect of the operator's hand. The patient's lower lip is drawn down with the right thumb, and the tip of the laryngoscope is introduced into the *right* side of the mouth. The blade is slid along the right side of the tongue, gradually displacing the tongue toward the left as the blade is moved to the center of the mouth. If the blade is initially placed in the middle of the tongue, the tongue will fold over the lateral edge of the blade and obscure the airway. Placing the blade in the middle of the tongue and failure to move the tongue to the left are two common errors preventing visualization of

the vocal cords (Fig. 2-7 *A-C*).

As the blade tip approaches the base of the tongue, the operator exerts a force along the axis of the laryngoscope handle, lifting upward and forward at a 45° angle. The epiglottis should come into view with this maneuver. It may help to have an assistant retract the cheek laterally to further expose the laryngeal structures. Do not bend the wrist; bending the wrist can result in dental injury because the teeth may be used as a fulcrum for the blade.

The step following visualization of the epiglottis depends on which laryngoscope blade is used. With the *curved* blade, the tip is placed into the vallecula, the space between the base of the tongue and the epiglottis. Continued anterior elevation of the base of the tongue and the epiglottis will expose the vocal cords. If the blade tip is inserted too deeply into the vallecula, the epiglottis may be pushed down to obscure the glottis. [6] When using the *straight* blade, the tip is inserted under and slightly beyond the epiglottis, directly lifting this structure. The jaw and larynx are literally suspended by the blade. If the straight blade is placed too deeply, the entire larynx may be elevated anteriorly and out of the field of vision. Gradual withdrawal of the blade should allow the laryngeal inlet to drop down into view. If the blade is deep and posterior, the lack of recognizable structures indicates esophageal passage; gradual withdrawal should permit the laryngeal inlet to come into view. The use of the curved and straight laryngoscope blades is illustrated in Figure 2-7 *D* and *E*.

Proper neck positioning and pressure (cephalad, dorsally, and rightward) on the larynx by an assistant will facilitate visualization and intubation of an anterior larynx. If needed, suctioning is performed at this point. If the vocal cords are still not seen, consider using a tracheal tube introducer (Smiths Industries Medical Systems, Keene, NH). This device, also known as the "elastic gum bougie," is a long, semirigid introducer that is placed, using the laryngoscope, through the laryngeal inlet and into the trachea. [12A] The tracheal tube is then passed over the introducer and the introducer is withdrawn. If resistance is met in passing the tracheal tube, rotate the tube 90° counterclockwise and advance the tube.

**Tube passage.**

Once the vocal cords have been visualized, the final and most important step, tube passage under direct vision through the vocal cords and into the trachea, is performed. The tube is held in the operator's right hand and introduced from the right side of the patient's mouth. The tube is advanced toward the patient's larynx at an angle, not parallel with or down the slot of the laryngoscope blade. This way, the operator's view of the larynx is not obstructed by the hand or the tube until the last possible moment before the tube enters the larynx. The tube should be passed during inspiration, when the vocal cords are maximally open. It enters the trachea when the cuff disappears through the vocal cords. The tube is advanced 3 to 4 cm beyond this point. It is not enough to see the tube and the cords; the tube must be seen *passing through* the vocal cords to ensure tracheal placement.

When the vocal cords are stimulated, laryngospasm-- the persistent contraction of the

adductor muscles of the vocal cords--may prevent passage of the tube. Inadequate anesthesia is often the cause. Pretreatment with topical lidocaine decreases the likelihood of this occurring. Two percent or 4lidocaine is sprayed directly on the cords. An infrequent but effective route for achieving tracheal anesthesia is via transtracheal puncture, injecting a bolus of 3 to 4 mL of lidocaine through the cricothyroid membrane. Laryngospasm is usually brief and is often followed by a gasp. The operator should be ready to pass the tube at this moment. Occasionally, the spasm is prolonged and needs to be broken with sustained anterior traction applied at the angles of the mandible--the jaw lift. At no time should the tube be forced, because permanent damage to the vocal cords may result. Consideration should be given to using a smaller tube. Prolonged, intense spasm may ultimately require muscle relaxation with a paralyzing drug (see Chapter 3) . The pediatric patient is far more prone to laryngospasm than is an adult. [12] In a child, if vocal cord spasm prevents tube passage, a chest thrust maneuver may momentarily open the passage and permit intubation.

**Positioning and securing the tube.**

The endotracheal tube should be secured in a position that minimizes both the chance of inadvertent endobronchial intubation and the risk of extubation. The tip should lie in the midtrachea with room to accommodate neck movement. Because tube movement with both neck flexion and extension averages 2 cm, the desired range of tip location is between 3 and 7 cm above the carina. [14]

On a radiograph, the tip of the tube should ideally be 5 ± 2 cm above the carina when the head and neck are in a neutral position. On a portable radiograph, the adult carina overlies the fifth, sixth, or seventh thoracic vertebral body. If the carina is not visible, it can be assumed that the tip of the tube is properly positioned if it is aligned with the T3 or T4 vertebra. In children, the carina is more cephalad than in the adult, but it is consistently situated between T3 and T5. In children, T1 is used as the reference point for the tip of the endotracheal tube. 44 [15]

An estimate of the proper depth of tube placement can be derived from the following formulas, the lengths representing the distance from the tube tip to the upper incisors in children  and from the upper incisors [18] or the corner of the mouth [19] in adults:

Adults: Tracheal tube depth (cm) = 21 cm (women)
Tracheal tube depth (cm) = 23 cm (men)

In adults, this method has been shown to be more reliable than auscultation in determining the correct depth of placement. [18]

The cuff is inflated to the point of minimal air leak with positive-pressure ventilation. In an emergency intubation, 10 mL of air is placed in the cuff, and inflation volume is adjusted after the patient's condition is stabilized.

After tracheal tube placement, both lungs are auscultated under positive-pressure ventilation. Care is taken to auscultate laterally because midline auscultation may lead

to an erroneous impression of tracheal placement when the tube is actually in the esophagus. With the tube in position and the cuff inflated, the tube is secured in place. Commercial endotracheal tube holders, adhesive tape, or umbilical (nonadhesive cloth) tape can be attached securely to the tube and around the patient's head (Figs. 2-8 and 2-9) (Figure Not Available) . The tube should be positioned in the corner of the mouth, where the tongue cannot expel it. This position is also more comfortable for the patient and allows for suctioning. A bite-block or oral airway to prevent endotracheal tube crimping or damage from biting is commonly incorporated into the system used to secure the tube.

### Infants and Children

Appreciation of the anatomic differences between children and adults is helpful when intubating the pediatric patient (Table 2-3 and Fig. 2-10) (Figure Not Available) . Infants' proportionately larger head naturally places them in the "sniffing position," so a towel under the occiput is rarely necessary. The large head can even result in a posterior positioning of the larynx that prevents visualization of the vocal cords; a small towel under the child's shoulders should correct this problem. The head also may be floppy, and it can be stabilized by an assistant during intubation. The child's increased tongue-to-oropharynx ratio and shorter neck hinder forward displacement of the tongue and, coupled with a long U-shaped epiglottis, can make visualization of the glottis difficult.

Consequently, direct laryngoscopy in the infant and young child is generally best performed with a straight blade: Miller size 0 for premature infants, size 1 for normal-sized infants, and size 2 for older children. The infant's larynx lies higher and relatively more anterior. One can have an assistant lightly apply laryngeal pressure, or the operator can use the little finger of the hand holding the laryngoscope blade for this purpose (Fig. 2-11) . If no laryngeal structures are visible after laryngeal pressure, the blade should be gradually withdrawn, because inadvertent advancement of the blade into the esophagus is a common error.

## Confirmation of Tracheal Intubation

### Clinical Assessment

The best assurance of tracheal placement is for the operator to see the tube pass through the vocal cords (Table 2-4) . Absent or diminished breath sounds, vocalization, increased abdominal size, and gurgling sounds during ventilation are clinical signs of esophageal placement. However, *esophageal placement is not always obvious*. One may hear "normal" breath sounds if only the midline of the thorax is auscultated. One way to clinically assess tracheal placement after a ventilation or during spontaneous respiration is to note whether air is felt or heard to exit through the tube following cuff inflation. If the tidal volume is adequate, the exit of air should be obvious. It is important to note that when an appropriately sized tube is placed in the trachea, the patient cannot groan, moan, or speak. Any vocalization suggests esophageal placement.

Asymmetrical breath sounds indicate probable main stem bronchus intubation. Due to

the angles of takeoff of the main bronchi and the fact that the carina lies to the left of the midline in adults, right main stem intubation is most common and is indicated by decreased breath sounds on the left side. When asymmetrical sounds are heard, the cuff should be deflated and the tube withdrawn until equal breath sounds are present. Bloch and colleagues report accurate pediatric tracheal positioning if after noting asymmetrical breath sounds, the tube is withdrawn a defined distance beyond the point at which equal breath sounds are first heard--2 cm in children younger than 5 years and 3 cm in older children. [20]

**Esophageal Detector Device**

An aspiration technique used to determine endotracheal tube location was first described by Wee in 1988. [21] The technique takes advantage of the difference in tracheal and esophageal resistance to collapse during aspiration to determine location of the tip of the tracheal tube. Following intubation, a large syringe is attached to the end of the endotracheal tube and the syringe plunger is withdrawn. If the tube is correctly placed in the trachea, the plunger will pull back without resistance as air is aspirated from the lungs. However, if the tracheal tube is in the esophagus, resistance is felt when the plunger is withdrawn, because the pliable walls of the esophagus collapse under the negative pressure and occlude the end of the tube. Another device using the same principle as syringe aspiration is the self-inflating bulb (e.g., Ellick's device).

Wee first reported use of an esophageal detector device in the operating room. [21] The tube was correctly identified in 99 of 100 cases (51 esophageal, 48 tracheal). The device result was considered equivocal in the remaining tracheal tube. The tube was removed and found to be nearly totally occluded with purulent secretions. Slight resistance was noted in one patient with a right main stem intubation; resistance decreased when the tube was pulled back. Before use, the esophageal detector device must always be checked for air leaks. If any connections are loose, the leak may allow the syringe to be easily withdrawn, mimicking tracheal location of the tube.

Wee recommends the following guidelines in using the aspiration technique: apply constant, slow aspiration to avoid tube occlusion from tracheal mucosa drawn up under high negative pressure. If the tracheal tube is correctly placed, 30 to 40 mL of air can be aspirated without resistance. If air was initially aspirated and then some resistance is encountered, the tracheal tube should be pulled back between 0.5 and 1.0 cm and partially rotated. This takes the tube out of the bronchus, if it has been placed too deeply, and changes the orientation of the bevel if the tube has been temporarily occluded with tracheal mucosa. Air is easily aspirated if the tube was in the trachea, but repositioning will make no difference if the tube was in the esophagus. The syringe aspiration technique can be used before or after ventilation of the patient. Continuous cricoid pressure should be applied pending tube confirmation. Inflation of the tube cuff will have no effect on the reliability of the test. [22] This device is reliable, rapid, inexpensive, and easy to use. Jenkins reported good success with physician use of the aspiration technique to confirm placement of emergency department and out-of-hospital intubations. [23]

A squeeze-bulb aspirator can be used as an alternative to the syringe technique. [24] [25]

The bulb is attached to the endotracheal tube and squeezed; if the tube is in the esophagus, it is often accompanied by a flatus-like sound followed by absent or markedly delayed refilling. Insufflation of a tube in the trachea is silent, with instantaneous refill. An early study with the Ellick's evacuator bulb device reported that 87% of esophageal tubes were identified. [24] A later study using a slightly different bulb device (Respironics, Murrysville,

| | | TABLE 2-3 -- Comparison of the Airway in the Adult and Child | |
|---|---|---|---|
| **Comparison** | **Child** | **Adult** | **Clinical Consequences or Adjustments for Child** |
| Head | Proportionately larger (up to about age 10 yr) | Proportionately smaller | Child naturally in sniffing position when supine; do not place towel under occiput; may benefit from elevation of shoulders; large head may be "floppy," requiring assistant to hold head still during intubation |
| Teeth | Easily knocked out | Stable unless decay or trauma is a factor | Teeth may be knocked out and aspirated or forced into trachea |
| Tonsils or adenoids | Large and friable | Generally not a problem | Nasotracheal intubation in child may cause excessive bleeding: adenoid or tonsil tissue may plug endotracheal tube or cause airway obstruction from aspiration |
| Tongue | Relatively large | Relatively smaller | Difficult to displace the tongue anteriorly in child: should consider using straight blade |

| | | | |
|---|---|---|---|
| Larynx | Opposite C2, C3 | Opposite C4-C6 | The more superiorly located larynx, the "anterior" larynx, is more difficult to visualize: consider using straight blade |
| Epiglottis | U-shaped, shorter, stiffer | Flatter, more flexible | Epiglottis more difficult to manipulate in child, may fold down and obstruct view with curved blade: consider using straight blade |
| Vocal cords | Concave upward. Anterior attachment of cords lower than posterior, creating a slant | Horizontal | Concave shape does not affect intubation, but it may affect ventilation: for partial airway obstruction or to break laryngospasm: consider positive pressure ventilation with jaw lift to open arytenoids; anterior superior slant of the vocal cords may cause the endotracheal tube to hang up on anterior commissure as it passes into larynx: rotate tube 90° counterclockwise Overextension of the neck may cause partial airway obstruction due to airway collapse |
| Length of trachea | Relatively short | Relatively longer | Short trachea increases likelihood of main stem bronchus intubation: follow the formula for correct depth of placement (cm depth = 0.5 age (yr) + 12) measured from the corner of the mouth; double black line on endotracheal tube should pass just beyond the cords |

| Airway diameter | Relatively smaller; smallest diameter is at the cricoid ring | Relatively larger; smallest diameter is between vocal cords | Laryngoscope-induced trauma, edema, and foreign material will significantly alter airway diameter: be gentle, extremes of flexion or extension may kink airway; if trouble with bag-valve-mask ventilation, reassess the degree of head flexion or extension; cricoid pressure may cause complete airway obstruction; endotracheal tube may pass through cords but be too small to pass through cricoid ring: if unable to pass into trachea, use the next smaller tube |
|---|---|---|---|
| Residual lung capacity | Relatively smaller | Relatively larger | Child may become hypoxic more quickly than adult. Closely monitor $O_2$ saturation and avoid prolonged periods without ventilation |

| **TABLE 2-4** -- Assessing Proper Tube Placement | |
|---|---|
| **Test** | **Interpretation** |
| Observe tube pass through the vocal cords | Accurate way to ensure placement; if in doubt, look again after intubation |
| Auscultation of breath sounds over the chest | May be misleading, especially if only midline is examined; listen in both axillae |
| Auscultation over the stomach | Gurgling indicates esophageal placement |

| | |
|---|---|
| Condensation (fog) forms inside tube with each breath | Quite reliable |
| Observe chest rise with positive pressure and fall with release | Generally reliable but may be absent in patients with small tidal volume or severe bronchospasm |
| Feel air exiting from end of tube following inflation | Reliable |
| Air remains in lung after end of tube is occluded and exits when occlusion is removed | Reliable but one may "ventilate" a closed area of the esophagus |
| Ask patient to speak; listen for moaning or other sounds | If tube is in proper place, no sound is possible |
| Chest radiograph | Generally reliable but can be misleading |
| End-tidal carbon dioxide measurements | Carbon dioxide not persistently detected if esophagus is intubated |
| Aspiration technique | Tracheal location with patent tube if 30-40 mL air is aspirated without resistance; probable esophageal location if unable to aspirate syringe easily or delayed bulb refill |
| Fiberoptic bronchoscope | Reliable if tracheal rings are seen down endotracheal tube |

| Lighted stylet down endotracheal tube | Reliable if transillumination seen in low midline neck |
| --- | --- |

Pa) found that all 45 esophageal tubes were detected. [25] The device is cheap and easy to use and can be operated single-handedly in <5 seconds.

Confusion may occur if the esophageal tube is tested more than once, because subsequent inflations may be silent. On repeated assessments, a false-positive refilling of the bulb may occur due to instillation of air during the first attempt. This observation has led to a recommendation that the bulb be compressed *before* it is attached to the endotracheal tube. Delayed though complete refilling may occur with bronchial tube placement or in the more pliable pediatric airway. The bulb suction modification of the aspiration technique has not been studied as thoroughly as the syringe technique.

**End-Tidal $CO_2$ Detector Devices**

A high level of $CO_2$ in exhaled gas is the physiologic basis for capnography and the principle on which end-tidal $CO_2$ ($ET_{CO_2}$) detectors was developed (see Chapters 6 and 16) . The most commonly available devices for emergency use are colorimetric indicators responding to $CO_2$ levels of gas flowing through the device when placed on the tracheal tube adapter. The typical device displays two extreme colors indicating a low level of $CO_2$ in esophageal intubation and another color in tracheal intubation. An intermediate color is indeterminate. Hand-held quantitative or semiquantitative electronic $CO_2$ monitors are also available.

A multicenter study of a colorimetric device demonstrated an overall sensitivity of 80% and a specificity of 96%. [26] In patients with spontaneous circulation and the tracheal tube cuff inflated, the sensitivity and specificity rose to 100%. The poor sensitivity seen in cardiac arrest (69%) is due to the fact that low exhaled $CO_2$ levels are seen in both very-low-flow states and in esophageal intubation. The device must therefore be used with caution in the cardiac arrest victim. Levels of $CO_2$ return to normal after return of spontaneous circulation in these patients. Further, colorimetric changes may be difficult to discern in reduced lighting situations, and secretions can interfere with the color change. Regardless of the monitoring device, patients in cardiac arrest should be ventilated for a minimum of 6 breaths prior to taking a reading, because recent ingestion of carbonated beverages can result in spuriously high $CO_2$ levels with esophageal intubation. [27]

**Comparison of Detector Devices**

In the setting of *spontaneous circulation*, both syringe aspiration and $ET_{CO_2}$ detection are highly reliable means of excluding esophageal intubation. A comparison of the techniques with clinical assessment was carried out in the animal laboratory, with measurement of the speed and accuracy of determination of tube placement. [28] Both

the syringe esophageal detector device and ET$co_2$ detection were highly accurate, approaching 100%. The esophageal detector device was more rapid with determination in 13.8 seconds vs 31.5 seconds for ET$co_2$ detection. The detector device remained accurate when air was insufflated into the esophagus for 1 minute, simulating unrecognized esophageal placement. Clinical assessment alone yielded an alarming 30% rate of misidentifying an esophageal tube as being in the trachea. In the setting of *cardiac arrest*, the aspiration method is more reliable than $CO_2$ detection, because its accuracy is not dependent on the presence of blood flow.

## Complications

Prolonged efforts to intubate may result not only in hypoxia but also in cardiac decompensation. Pharyngeal stimulation can produce profound bradycardia or asystole; when it is feasible, an assistant should view the cardiac monitor during intubation of a patient who has not suffered cardiac arrest. Atropine should be available to reverse vagal-induced bradycardia that may occur secondary to suctioning or laryngoscopy. Prolonged pharyngeal stimulation also may result in laryngospasm, bronchospasm, and apnea.

The maximum interval allowable for routine intubation of the apneic patient is 30 seconds. As a guide, one should limit the time of an intubation attempt to the amount of time a single deep breath can be held. This is especially important in a child, because the functional residual capacity of a child's lungs is less than that of an adult. Failure to achieve control within this time frame demands an interval of bag-valve-mask ventilation before intubation is attempted again. The use of preoxygenation to minimize hypoxia is strongly recommended. An oxygen saturation monitor can also be used to monitor explicitly for hypoxia. Assuming optimal preoxygenation of the patient to >98% $O_2$ saturation, attempts at intubation should be halted until the patient is reoxygenated whenever the $O_2$ saturation drops below 92%, equal to a P$O_2$ of about 60 to 65 mm Hg. When ventilation is not achievable, irreversible brain damage can result within minutes. Therefore, the maximum interval allowable for conservative airway management maneuvers is about 3 minutes; one must then choose alternative methods (see Chapter 1 and 4) .

One should check for loose or missing teeth before and after orotracheal intubation. Any avulsed teeth not found in the oral cavity warrant a postlaryngoscopy chest film to rule out aspiration of a tooth. Swallowed teeth are of no consequence. In a study of 366 patients, McGovern and coworkers found broken teeth to be the most common complication of laryngoscopy. [29] Laceration of the mucosa of the lips, especially the lower lip, may occur if adequate care is not taken. Tracheal or bronchial injuries are rare but serious, usually occurring in infants and the elderly as a result of decreased tissue elasticity. [30] Vomiting with aspiration of gastric contents is another serious complication that can occur during intubation.

The most devastating complication of tracheal intubation is unrecognized esophageal intubation. Assessment of tube position should be the first step in the emergency department evaluation of patients who have undergone out-of-hospital intubation. The best assurance of tracheal placement is for the operator to see the tube pass through

the vocal cords. Techniques to assess tube placement are discussed earlier. Another method of reliably determining tracheal tube location uses the fiberoptic scope. Passage of the scope through the tube with visualization of tracheal rings confirms endotracheal placement as well as the position within the trachea. The placement of a lighted stylet down the tracheal tube and successful transtracheal illumination also reliably predicts tracheal positioning. [31]

A chest radiograph should be taken shortly after the intubation to confirm tube placement and position. Bissinger and coworkers noted that endobronchial intubation was clinically unrecognized without a chest film in 7% of out-of-hospital intubations. [32] In addition to hypoxia, delayed tube repositioning can lead to unilateral pulmonary edema. [33] Persistent asymmetrical breath sounds after appropriate tube positioning suggests unilateral pulmonary pathology (e.g., main stem bronchus obstruction, pneumothorax, or hemothorax).

If an endotracheal tube is removed from the esophagus, vomiting may occur. This should be anticipated and suction readied. Cricoid pressure should be applied during tube removal and maintained until intubation is successful. Alternatively, the first tube can be left in the esophagus to serve as temporary gastric venting until tracheal intubation is achieved.

A persistent air leak during ventilation usually means one of three things: (1) the cuff is leaking because of damage to the balloon, (2) the cuff is positioned above or between the vocal cords, or (3) the pilot balloon is leaking. If the cuff is leaking, the tracheal tube must be replaced (see Changing Tracheal Tubes). If the pilot balloon is determined to be leaking, however, this can usually be remedied without changing the tube. [34] An incompetent 1-way balloon valve can be fixed by placing a stopcock into the inflating valve. Reinflation of the cuff followed by shutting off the stopcock should solve the problem. If the leak involves the pilot balloon itself, or if the distal inflation tube has been inadvertently severed, cut off the defective part and slide a 20-ga catheter into the inflation tube. Then connect the stopcock to the catheter, inflate the cuff, and close the stopcock.

Tracheal stricture used to be a significant late complication of long-term intubation with low-volume high-pressure cuffs. The standard use of high-volume low-pressure cuffs has markedly decreased the incidence of this complication. [35] Tubes with high-pressure cuffs are obsolete and should be avoided.

**Summary**

Orotracheal intubation is the mainstay of definitive airway management. In the comatose patient, it is usually accomplished rapidly and without difficulty. The easy intubation is frequently successful in the hands of the novice; the difficult intubation often proves challenging even for the experienced operator. Rapid-sequence intubation has increased the use of orotracheal intubation as the first-line approach in a variety of clinical situations and settings (see Chapter 3) . Once the patient's breathing and protective reflexes are removed, however, the operator has the supreme responsibility of safely reestablishing them. A mastery of the technique of orotracheal intubation is

essential.

# MODIFIED OROTRACHEAL INTUBATION

## Intubation with an Intermediate Airway in Place

### Esophageal Obturator/Gastric Tube Airway in Place

The unconscious patient who requires ventilatory assistance may benefit from the temporary use of the esophageal obturator

airway (EOA) or similar device, as described in Chapter 1 . Although this may be an effective means of ventilation, it is at best a temporary measure. The patient experiencing upper airway hemorrhage with the EOA in place may have oropharyngeal blood insufflated into the trachea. Also, an endotracheal tube is the preferred airway, because with endotracheal intubation the airway is more secure and ventilation more convenient. Although the EOA may allow rapid airway support until cervical spine injury can be ruled out, it is recommended that the EOA not be left in place for more than 2 hours.

Replacement of the EOA with an orotracheal tube requires appropriate care. Removal of the esophageal cuff before placement of the endotracheal tube is fraught with danger. Spontaneous gastric regurgitation often occurs on EOA removal. The rescuer must therefore learn to perform endotracheal intubation around the EOA to protect the patient from aspiration.

The patient is hyperventilated through the EOA before intubation is attempted around it. The EOA mask is then removed, and the EOA tube is moved to the *left* side of the patient's mouth. Laryngoscopy and intubation are then performed in the usual fashion. If resistance to passage of the tracheal tube is met, the volume of the EOA balloon should be reduced, because the balloon may be producing distortion of the larynx. Next, the operator deflates the EOA balloon completely and slides it out of the patient's esophagus. If resistance is met, the operator must be sure that the esophageal cuff has been deflated completely.

### Esophageal-Tracheal Combitube (ETC) in Place

Combitubes placed in the esophagus will generally require replacement with a tracheal tube. The inflated pharyngeal balloon prevents tracheal intubation around this airway. This proximal balloon must be deflated before attempting tracheal intubation. If intubation is still not possible, the ETC may need to be removed; the stomach should first be emptied via a gastric tube placed through the esophageal port of the airway. Suction is readied, the distal balloon is deflated, and the patient is quickly intubated. This maneuver poses an added risk over that associated with the esophageal obturator intermediate airway placement (i.e., EOA and EGTA--see Chapter 1) .

**Laryngeal Mask Airway in Place**

The trachea can often be intubated with the laryngeal mask airway (LMA) left in place. The various approaches to intubation with an LMA in place are discussed in Chapter 1 (see Figs. 1-10 (Figure Not Available) and 1-11) (Figure Not Available) .

## Bullard Laryngoscope Use

A recent development for intubating the difficult airway is the Bullard laryngoscope, an anatomically shaped rigid fiberoptic laryngoscope that provides an indirect view of the larynx (Fig. 2-12) (Figure Not Available) . It was design`ed to aid in intubating the difficult airway; and because no manipulation of the neck is necessary, it is especially well suited for the patient with potential cervical spine injury. Indeed, in the anesthetized patient, the Bullard laryngoscope has been found to cause less head extension and cervical spine extension than conventional laryngoscopes do. [36] The recent addition of an intubating stylet attached to the laryngoscope has resulted in increased ease and speed of intubation, and the technique appears to be effective regardless of the patient's head and neck anatomy. [37] Because alignment of the oropharyngeal and laryngeal axes is not required, the Bullard laryngoscope offers the advantage provided by a conventional fiberoptic scope but requires less training to gain proficiency in its use. [38]

**Indications and Contraindications**

The Bullard laryngoscope is indicated in patients with anticipated difficult airways who require definitive airway control. It can be used in awake as well as unresponsive patients. [39] The total inability to open the mouth is a contraindication to the use of this laryngoscope. However, because the Bullard laryngoscope follows the contour of the mouth and hypopharynx, only 2 cm of occlusal opening is necessary for the introduction of the scope plus endotracheal tube for intubation.

**Procedure**

The technique for introducing the Bullard laryngoscope blade is similar to that for direct laryngoscopy. The operator, who is at the head of the patient, opens the mouth with the left thumb while holding the head stable. As the scope blade is introduced into the oropharynx, the handle is rotated to follow the curve of the hypopharynx until the handle is fully vertical. The tip of the blade can be used to lift the epiglottis, but visualization of the larynx is usually possible without this maneuver. Only minimal force is exerted along the axis of the handle. Intubation of the larynx can be accomplished using a styletted endotracheal tube or an endotracheal tube with a directional tip (Endotrol; Mallinckrodt, Critical Care, Glens Falls, NY). The technique is generally successful when using the new Bullard intubating stylet. [37]

Awake intubation using the Bullard laryngoscope can be performed comfortably using topical anesthesia and light IV sedation. [39] Adult and pediatric Bullard laryngoscopes

are available, and the scope has been used successfully in neonates. [38] The Bullard scope can also be used in conjunction with nasotracheal intubation and has the advantage of requiring only 6 mm of mouth opening through which to insert the blade. [40]

### Complications

The major difficulty in using the Bullard laryngoscope is the inability to visualize the larynx because of blood, emesis, or secretions. Another reason for failure is the inability to place the blade tip under the epiglottis. [37]

### Summary

The Bullard scope is useful in the difficult airway uncomplicated by blood and excessive secretions. In the all-too-common setting of blood and secretions, however, the inability to visualize the vocal cords significantly limits the utility of this device in emergency airway management.

## NASOTRACHEAL INTUBATION

Nasotracheal intubation was first described by Magill in the 1920s and the basic technique has changed little over the years. Modifications have been described that increase the success rate and limit complications. The tube may be placed blindly or with the aid of a laryngoscope or bronchoscope. Blind nasotracheal intubation can be one of the more technically demanding airway approaches, with the outcome being heavily dependent on the skill and experience of the operator. The primary advantage of blind nasotracheal intubation is that it minimizes neck movement and does not require opening the mouth.

### General Indications and Contraindications

Nasotracheal intubation is technically more difficult than oral intubation, but it has definite advantages. It is especially suitable for the patient with a short, thick neck or other anatomic characteristics that would make orotracheal intubation difficult. Patients with clenched teeth or suspected cervical spine injury can be intubated with minimal preparation. Cervical spine films, jaw spreading, or paralyzing agents as preliminaries to airway control are unnecessary.

Blind nasotracheal intubation is possible with the patient in the sitting position, a distinct advantage when intubating the patient with congestive heart failure who cannot tolerate lying flat. In fact, patients in respiratory distress are the easiest to intubate blindly because their air hunger results in increased abduction of the vocal cords, which facilitates tube entry into the trachea. The drug overdose patient with a decreased level of consciousness is a candidate for nasotracheal intubation. These patients are often intubated before gastric lavage and may be sufficiently awake to make orotracheal intubation difficult without paralyzing agents.

A nasotracheal tube has advantages that extend beyond the immediate difficulties of airway control. The patient cannot bite the tube or manipulate it with the tongue. Oral injuries may be cared for without interference by the tube. A nasotracheal tube is more easily stabilized and generally easier to care for than an orotracheal tube. It is better tolerated by the patient, permitting easier movement in bed, and produces less reflex salivation than do oral tubes.

Nasal intubation should be avoided in patients with severe nasal or midface trauma. In the presence of a basilar skull fracture, a nasotracheal tube may inadvertently enter the brain through a basilar skull fracture. [41] The technique should be avoided in patients in whom thrombolytic therapy is being considered. Nasal intubation is relatively contraindicated if the patient is taking anticoagulants or is known to have a coagulopathy.

## Blind Placement

Blind nasotracheal intubation is the most common form of nasotracheal intubation in the emergency setting. Danzl and Thomas reported a success rate of 92% in a large series of emergency department patients. [42]

### Indications and Contraindications

Any patient requiring airway control who has spontaneous respirations is a candidate for blind nasotracheal intubation. Specific indications that favor this approach over others are (1) short, thick neck, (2) inability to open the mouth, (3) inability to move the neck, (4) gagging or resisting the use of the laryngoscope, and (5) oral injuries.

Apnea is the major contraindication to blind nasotracheal intubation. Attempts to place the tube without respirations as a guide are futile. Relative contraindications include basilar skull fracture and nasal injury. [41] [43] Furthermore, significant bleeding may occur if the patient is receiving anticoagulants or has a coagulopathy. Blind nasotracheal intubation should be avoided in patients with expanding neck hematomas. Patient combativeness, if not controlled with sedation, is also a contraindication.

Some would argue that the inability to open the mouth is a relative contraindication, because emesis may be induced that could not be cleared. The operator must exercise judgment in the individual case and be prepared to use neuromuscular blocking agents or to bypass the upper airway with a surgical technique if such a complication develops.

### Procedure

The patient is placed in the "sniffing" position with the proximal neck slightly flexed and the head extended on the neck. In preparation for intubation, the operator constricts the nasal mucosa of both nares, using either 0.25 to 1.0% phenylephrine drops, oxymetazoline (Afrin) spray, or 4% cocaine spray. Topical anesthesia of the nares, oropharynx, and hypopharynx with lidocaine spray (10%) is also indicated if time

permits. If available, cocaine is ideal because it is both a vasoconstrictor and an anesthetic; caution is necessary in hypertensive patients. The most patent nostril is chosen. In the cooperative patient, this can be determined simply by occluding each nostril and asking the patient which one is easier to breathe through. The most patent nostril can also be identified by direct vision, or by gently inserting a gloved finger lubricated with viscous lidocaine, full length into the nostrils. If time is not an issue, an effective method to dilate the nasal cavity and administer the anesthetic is to pass a lidocaine gel-lubricated nasopharyngeal airway (nasal trumpet) into the selected nostril. This

airway is left in place for several minutes, and progressively larger trumpets are introduced.

After preparation of the nostril, a well-lubricated endotracheal tube with a 7.0 or 7.5 mm ID is inserted along the floor of the nasal cavity. The tube is *not* directed cephalad, as one might expect from the external nasal anatomy, but rather is directed straight back toward the occiput, corresponding with the nasal floor. Twisting the tube may help bypass soft tissue obstruction in the nasal cavity. It is sometimes recommended that the bevel of the tube be oriented toward the septum to avoid injury to the inferior turbinate. However, such an event is rare. At 6 to 7 cm, one usually feels a "give" as the tube passes the nasal choana and negotiates the abrupt 90° curve required to enter the nasopharynx. This is the most painful and traumatic part of the procedure and must be done gently. If resistance is encountered that persists despite continued gentle pressure and twisting of the tube, the passage of a suction catheter down the tube and into the oropharynx may allow for successful passage of the tube over the catheter. [44] If this fails, the other nostril should be tried. In an attempt to avoid this difficulty from the outset, a controllable-tip tracheal tube (Endotrol, Mallinckrodt Medical Inc, St Louis) may be used that allows the operator to increase the flexion of the tube and facilitates passage past this tight curve. One study found the Endotrol tube to enhance first attempt success with blind nasotracheal intubation. [45]

As the tube is advanced through the oropharynx and hypopharynx and approaches the vocal cords, breath sounds from the tube become louder, and fogging of the tube may occur. At the point of maximal breath sounds, the tube is lying immediately in front of the laryngeal inlet. The tube is most easily advanced into the trachea during inspiration because that is when the vocal cords are maximally open. As the patient begins to breathe in, the tube is advanced in one smooth motion. If a gag reflex is present, the patient usually coughs and becomes stridulous during this maneuver, suggesting successful tracheal intubation. The absence of such a response should alert the operator to probable esophageal passage. If there is a delay in advancing the tube, oxygen can be added to the end of the tube to increase inspired oxygen. Once the tube is in the trachea, moaning and groaning should cease. If they continue, esophageal intubation is likely. Breath sounds coming from the tube and tube fogging are other signs of endotracheal placement. Reflex swallowing during blind nasotracheal intubation may direct the tube posteriorly toward the esophagus. If this occurs, the conscious patient should be directed to stick out the tongue to inhibit swallowing and prevent consequent movement of the larynx. Application of laryngeal pressure may also help

avoid esophageal passage.

Following intubation, both lungs are auscultated while positive-pressure ventilation is applied. If only one lung is being ventilated, the tube is withdrawn until breath sounds are heard bilaterally. The optimum distance from the external nares to the tube tip is about 28 cm in males and 26 cm in females. [45A] After verification of tracheal placement, the cuff is inflated and the tube is secured.

**Technical Difficulties**

The nasotracheal tube may slide smoothly through the hypopharynx and into the trachea on the first pass. Unfortunately, this is not always the case; in the operating room, the first attempt was successful in <50% of cases. [46] When the initial pass is unsuccessful, there are 4 potential locations of the tip of the tube: (1) anterior to the epiglottis in the vallecula, (2) on the arytenoid or vocal cord, (3) in the piriform sinuses, or (4) in the esophagus.

Observation and palpation of the soft tissues of the neck during attempted passage of the nasotracheal tube are helpful in determining the location of the misplaced tube. This is ideally done by the operator but may also be performed by an experienced attendant. Before reattempting placement, the tube is withdrawn slightly; it is not removed from the nose, because this will create additional trauma to the nasal soft tissues. The possibility of cervical spine injury must be kept in mind when considering corrective maneuvers. Any maneuver that moves the neck significantly should not be used if alternatives are available. Methods for achieving success when difficulties with tube placement are encountered include the following:

**Anterior to the epiglottis.**

Difficulty advancing the tube beyond 15 cm or palpation of the tube tip anteriorly at the level of the hyoid bone suggests an impasse anterior to the epiglottis in the vallecula. Withdrawing the tube 2 cm, decreasing the degree of neck extension, and readvancing the tube will frequently remedy this problem.

**Arytenoid cartilage and vocal cord.**

Contrary to the classic teaching, [47] recent studies have demonstrated a propensity for a nasotracheal tube, when placed through the right nares, to lie posteriorly and to the right as it approaches the larynx. [40] [48] It is not surprising, then, that the most common obstacles to advancement of the nasotracheal tube are the right arytenoid and vocal cord. No data are available on the common obstacles encountered if the tube is placed in the left nares. If the tube appears to be hanging up on firm, cartilaginous tissue, withdraw the tube 2 cm, rotate it 90° counterclockwise, and readvance the tube. This maneuver orients the bevel of the tube posteriorly and frequently results in successful passage (Fig. 2-13) (Figure Not Available) . Another technique is to pass a suction catheter down the tube; it often will pass through the larynx without difficulty and the

tube can then be advanced over the catheter (Fig. 2-14) (Figure Not Available) . [49] [50]

**Piriform sinus.**

Bulging of the neck lateral and superior to the larynx indicates tube location in a piriform sinus. The tube should be withdrawn 2 cm, rotated slightly away from the bulge, and readvanced. An alternate method is to tilt the patient's head toward the side of the misplacement and reattempt placement. [51]

**Esophageal placement.**

Esophageal placement is indicated by a smooth passage of the tube with the loss of breath sounds. The larynx may be seen or felt to elevate as the tube passes under it. Assisted ventilation will usually produce gurgling sounds when the epigastrium is auscultated. The tube should be withdrawn until breath sounds are clearly heard, and passage should be reattempted while pressure is applied to the cricoid. Increased extension of the head on the neck during placement may help. If attempts continue to result in esophageal misplacement, the following maneuver may result in successful tracheal intubation: from the precise point at which breath sounds are lost, the endotracheal tube is withdrawn 1 cm. The cuff is inflated with 15 mm of air, resulting in an elevation of the tube off the posterior pharyngeal wall and angling it toward the larynx. The tube is then advanced 2 cm; continued breath sounds indicate probable intralaryngeal location. At this point, the cuff is deflated and the endotracheal tube is advanced into the trachea (Fig. 2-15) (Figure Not Available) . This technique may be particularly useful in the patient with cervical spine injury, because it requires no manipulation of the head or neck. [52] This maneuver, when used on the *first* pass in 20 patients in the operating room, was successful in 75% of cases. [46] One should bear in mind, however, that these patients were paralyzed and thus did not experience the laryngospasm that may be encountered in a breathing patient. The use of topical anesthesia is recommended. Alternatively, if a controllable-tip endotracheal tube (Endotrol) is used, the tip can be flexed anteriorly to help avoid esophageal placement. [45] Remember that the tip is very responsive to pulling on the ring. A common mistake is to exert too much force on the ring, resulting in the tube curling up short of the larynx, thus preventing tube advancement.

**Laryngospasm.**

Laryngospasm is common when attempting nasotracheal intubation. It is usually transient. The tube is withdrawn slightly and the operator should wait for the patient's first gasp; advancement of the tube at this precise moment is frequently successful, as the vocal cords are widely abducted during forced inhalation. Laryngeal anesthesia should also be assessed, and if IV and nebulized lidocaine have already been administered without success, transcricothyroid anesthesia (e.g., 2 mL of 4% lidocaine) should be considered. [53] Occasionally, a jaw lift is necessary to break prolonged spasm. Another option is to use a smaller tube.

**Placement Under Direct Vision**

This technique combines elements of oral and nasotracheal intubation. The indications and precautions are similar, and the importance of considering cervical spine injury is identical. Likewise, the need for jaw opening by physical or pharmacologic means is unchanged. This method is preferred to orotracheal intubation if the presence of an orotracheal tube might interfere with the repair of an oral injury. It is also useful when blind nasotracheal intubation has failed.

Preparation of the nose and nasopharynx and passage of the tube into the oropharynx are the same as described for blind nasotracheal intubation. It is with the introduction of the laryngoscope that the technique changes.

Laryngoscopy, as described with orotracheal intubation, is used to visualize the vocal cords and the tip of the endotracheal tube. With the Magill forceps in the right hand, the endotracheal tube is grasped proximal to the cuff (to avoid damage to the balloon) and directed toward the larynx (Fig. 2-16) . An assistant advances the tube gently while the operator directs the tip into the larynx and trachea. Cricoid pressure may facilitate the passage. Often the larynx can be manipulated sufficiently with the laryngoscope so that the physician can advance the tube with the right hand and guide it between the cords without using the Magill forceps. Occasionally, the natural curve of the tracheal tube guides it through the cords without any manipulation. The cuff is inflated, and both lungs are auscultated to ensure ventilation. When placement is satisfactory, the tube is secured.

**Complications**

Epistaxis is the most common complication of nasotracheal intubation. However *severe* epistaxis was encountered in only 5 of 300 cases reported by Danzl and Thomas. [42] Tintinalli and Claffey reported severe bleeding in 1 of 71 cases and less serious bleeding in 12 others. [54] Bleeding is usually not a problem unless it provokes vomiting or aspiration, a serious potential problem in obtunded patients with a clenched jaw or a decreased gag reflex. Other immediate complications include turbinate fracture, intracranial placement through basilar skull fracture, retropharyngeal laceration or dissection, and delayed or unsuccessful placement.  Unsuccessful placement may be minimized by selection of a smaller tube and by gentle technique.

Sinusitis in patients with nasotracheal tubes is common and can be an unrecognized cause of sepsis. [58] Rare but potentially fatal delayed complications include mediastinitis following retropharyngeal abscess [59] and massive pneumocephalus. [60]

Because most of the complications occur during tube advancement through the nasal passage and proximal nasopharynx, the complications of blind nasotracheal intubation and placement under direct vision are largely the same. However, retropharyngeal laceration and esophageal intubation are more of a threat in blind placement techniques because they are more likely to go unrecognized. [54] One unique problem associated

with nasotracheal intubation is damage of the tube cuff with the Magill forceps.

Delayed nasotracheal placement under direct vision deserves special discussion. Manipulation of the endotracheal tube through the nose and with the Magill forceps during the direct vision technique involves additional steps that require time. Because time is of the essence in the resuscitation of the critically ill patient, orotracheal intubation may be preferable.

**Summary**

Nasotracheal intubation is being used less frequently than in the past, because practitioners are increasingly comfortable using oral intubation in the patient with potential cervical spine injury. In addition, emergency physicians frequently use paralytics to facilitate orotracheal intubation. Nevertheless, nasotracheal intubation remains an effective and potentially life saving approach to the difficult airway and should be a dependable part of the armamentarium of all providers who are active in emergency airway management.

# GUIDED INTUBATION TECHNIQUES

## Digital Intubation

Digital intubation is a technique that uses the index and middle finger to blindly direct the endotracheal tube into the larynx. It is particularly well adapted to the out-of-hospital situation in which a trapped victim cannot be positioned for intubation. An out-of-hospital series of 66 digitally intubated patients demonstrated an 89% success rate. [61]

**Indications and Contraindications**

Digital intubation is indicated in the deeply comatose patient whose larynx cannot be visualized and who has a contraindication to nasotracheal intubation. Advantages include speed and ease of placement, immunity to anatomic constraints and other difficulties visualizing the larynx, and little neck movement. Contraindications are primarily precautions to protect the operator: digital intubation should not be attempted on any patient who presents a significant risk of biting. This includes the calm and awake patient as well as the agitated patient.

**Procedure**

The patient's head and neck are placed in neutral position. The operator stands at the patient's right side, facing the patient. The operator's left index and middle fingers are introduced into the right angle of the patient's mouth and are slid along the surface of the tongue until the epiglottis is palpated. The tip of epiglottis is palpated at 8 to 10 cm from the corner of the mouth in the average adult. The use of a stylet in the tube is optional; the largest reported series had good success without a stylet. [61] For the operator with short fingers or a patient with an anterior larynx, a stylet is advantageous. If a stylet is used, it is placed in the tube and bent into the form of an open "J" with the

distal end terminating in a gentle hook. A lubricated tube is introduced from the patient's left between the tongue and the rescuer's 2 fingers (Fig. 2-17) (Figure Not Available) . The tube is cradled between 2 fingers and the tip is guided beneath the epiglottis. Gentle anterior pressure directs the tube into the larynx. If the operator has sufficiently long fingers, they can be placed posterior to the arytenoids, acting as a "backstop" for the tube to both avoid esophageal passage and to assist in laryngeal placement. [62] If a stylet has been used, it is withdrawn at this time while simultaneously advancing the tube. An alternative to using a stylet for directing the tube anteriorly is to select an endotracheal tube with a controllable tip (Endotrol, Mallinckrodt Medical Inc, St Louis).

A variation on the technique of digital intubation has been described for intubating the newborn. [63] Only the index finger is used to guide the tube intraorally into the larynx. The end of the tube is bent and both the tube and the finger are moistened with sterile water. The index finger of the nondominant hand follows the tongue posteriorly to easily palpate the epiglottis and paired arytenoid. The thumb of the same hand may be used to apply cricoid pressure to steady the larynx. The endotracheal tube is held in the dominant hand and advanced using the nondominant index finger as a guide (Fig. 2-18) (Figure Not Available) . The tube snugs up (encounters subtle resistance) as it enters the trachea, and palpation of the tube through the trachea provides further confirmation of correct placement. A styletted tube, shaped in the form of a J, is usually desired until familiarity with the procedure is achieved.

### Complications

The risk of esophageal intubation is always present and, being a blind procedure in deeply comatose or cardiac arrested patients, the potential for esophageal misplacement is increased. If used in patients with a gag, induction of emesis with aspiration is a possibility. A high incidence of left main stem intubations was noted in a cadaveric study, [64] but clinical confirmation is lacking. The greatest risk seems to be to the operator, whose fingers may be bitten.

### Summary

While most of the recent experience with digital intubation in adults has been out of hospital, there is no reason why it should be confined to this setting. The majority of moribund emergency department patients who defy orotracheal intubation are never given a trial of digital intubation. This omission undoubtedly deprives some patients of expeditious airway management.

## Lighted Stylet Intubation

This technique uses a battery-operated lighted stylet that is placed in an endotracheal tube and used to guide the tube into the trachea by transilluminating the soft tissues of the neck. First described in 1957 by MacIntosh and Richards, [65] it was designed to aid in intubating the difficult airway. It has also been shown to be a useful means of determining the position of the tracheal tube. [31]

In the operating room, the Tube Stat lighted stylet (Concept Corp, Clearwater, Fla) has been 99 to 100% successful. [66] [67] The requirement that the overhead lights be dimmed during the procedure has limited its use in most emergency settings. In a small out-of-hospital study, 88% of patients were successfully intubated by physicians using a lighted stylet. [68] The majority of the failures occurred in the setting of bright sunlight and in patients who had vomited. A new device (Trachlight, Laerdal, Inc, Starger, Norway) with a brighter light source and adjustable length, appears to have solved this problem. In a series of 96 patients, many with a history of difficult intubation, all but 1 were successfully intubated in ambient light with this device using either the oral or nasotracheal route. [69] Consistent with other series, the only failure was in a morbidly obese patient.

**Indications and Contraindications**

The patient with a difficult airway in whom direct laryngoscopy has failed is a candidate for light-guided tracheal intubation. A multiple trauma patient with airway bleeding is a prime example. The patient who has been pharmacologically paralyzed and cannot be intubated with direct laryngoscopy is another example. The lighted stylet may also be helpful in successfully completing a difficult nasotracheal intubation. One advantage of this technique over nasotracheal intubation is that it can be used in the apneic patient.

Because lighted stylet intubation is a blind approach, it should be avoided in patients with expanding neck masses and patients with airway compromise presumed due to a foreign body. Massive obesity has been shown to be the most common cause for failure with this technique because of the impossibility of transilluminating through the generous soft tissue.

**Preparation**

The function of the bulb of the lighted stylet should be checked before use. The patient's head should be placed in a neutral or, if cervical spine injury is not a concern, the sniffing position. The awake patient should have the oropharynx and hypopharynx sprayed with lidocaine and sedation should be administered as indicated.

**Procedure**

The lubricated lighted stylet is inserted into a tracheal tube (5.5 mm or larger) until the bulb lies just distal to the side port, not protruding from the end of the tube. This unit is bent in the shape of a hockey stick that approximates a 90° curve beginning just proximal to the tube cuff. The operator stands at the head of the patient. When this is not possible, the patient can be approached from the right or the left side. The tongue is grasped with gauze and pulled forward. Another means of exposing the oropharynx is to grasp the jaw between the thumb and the fingers (Fig. 2-19) (Figure Not Available) . The light is turned on and the unit is inserted into the mouth, following the curve of the tongue into the oropharynx. A transilluminating glow indicates the location of the tube tip. Application of cricoid pressure may enhance transillumination. [31] The overhead light

should routinely be dimmed if feasible. Positioning is optimal when the glow emanates from the midline at the level of the hyoid bone. Holding the lighted stylet steady, the tube is slid off and advanced into the trachea. If the glow is located elsewhere, the unit should be withdrawn 2 cm or cocked back and repositioned as indicated by the light. If no light is seen, the tube is in the esophagus and should be pulled back, laryngeal pressure applied, and, if necessary, the head extended slightly. After passage, the tube should be checked for correct positioning and then secured.

**Complications**

Earlier reports noted complications resulting from an equipment failure and lost bulbs, but these problems have been corrected. No complications have been noted in the recent literature, but this may only reflect the limited use of this technique in uncontrolled settings.

**Summary**

Lighted stylet intubation is a safe, rapid, and highly successful method that has a definite place in the management of the difficult airway. Recent improvements in the device will increase its applicability to most settings in which emergency airway control is required.

## Intubation over a Fiberoptic Bronchoscope

The use of the flexible fiberoptic bronchoscope as an aid to tracheal intubation is a recent addition in airway management in the emergency department. In this setting, success approximates 80%, with the most common cause of failure being the inability to visualize the glottis secondary to blood and secretions. [70] [71]

Flexible fiberoptic endoscopy is the best method for intubating the awake patient with a difficult airway. It can be accomplished using the nasal or oral route and is better tolerated than direct laryngoscopy. It also may be effective in the comatose patient when more conventional methods have failed. It provides excellent visualization of the airway and permits the evaluation of the airway prior to tube placement. The greatest obstacle to success is the inability to see through the scope secondary to blood, secretions, or fogging. The expense of the equipment, its fragility, and the time required to achieve technical proficiency are three other drawbacks.

**Indications and Contraindications**

Common indications for emergency fiberoptic intubation include the unstable cervical spine, expanding neck masses, upper airway infection, facial and airway burns, and anticipation of a difficult intubation due to anatomic constraints. It may also be helpful in guiding blind nasotracheal intubation that is initially unsuccessful.

Contraindications to fiberoptic nasotracheal intubation are those ascribed to nasotracheal intubation in general: severe midface trauma and coagulopathy. Although

there are no clear contraindications to fiberoptic orotracheal intubation, active airway bleeding and vomiting are relative contraindications because successful fiberoptic intubation is rarely achieved in this setting. If the operator is inexperienced in fiberoptic intubation, apnea is another relative contraindication to its use.

**Equipment**

Fiberoptic scopes are graded according to their external diameter (in millimeters). A convenient intubating scope is 3.5 mm. Although it is physically possible to pass a 4.0 mm (0.5 mm larger) tracheal tube over the scope, the fit is quite tight. As a rule, the tracheal tube should be at least 1 mm larger than the intubating scope. The size of the working channel--the port to which suction or oxygen is applied and through which fluid or catheters may be passed--is another important dimension when evaluating fiberoptic scopes. Large working channels are desirable.

**Procedure**

The optimal positioning of the neck is in extension, as opposed to the cervical flexion desired when using direct laryngoscopy. Extension allows for better visualization of the

glottis by elevating the epiglottis off the posterior pharyngeal wall. This is especially pertinent in the comatose patient who lacks the muscle tone necessary to maintain an open airway. Problems with the tongue and soft tissues falling back and obscuring fiberoptic scope view are effectively managed by applying a jaw lift or pulling the tongue forward and away from the soft palate and posterior pharyngeal wall. This maneuver also moves the epiglottis away from the posterior pharyngeal wall facilitating exposure of the cords. Extending the head on the neck may accomplish the same objective.

**Nasotracheal approach.**

The nasal approach is preferred to the oral approach because the angle of insertion allows for easier visualization of the larynx and because patient cooperation is not as critical. Also, in the unconscious patient, the tip of the scope is less likely to impinge on the base of the tongue with a nasal approach.

The nose is prepared using a vasoconstrictor and topical anesthetic agent as described for nasotracheal intubation. Using an aerosolized anesthetic agent, it is important to obtain sufficient hypopharyngeal anesthesia to minimize gagging and laryngospasm once the procedure begins. The well-lubricated endotracheal tube may be placed in the nostril first, and the scope passed through it, or the endotracheal tube can be mounted over the scope and the scope first passed through the nostril. The advantage of the former is that it avoids the possibility of nasal secretions covering the scope and obscuring the view. The disadvantage is that nasotracheal placement may cause bleeding as well as that in some patients, the tube may not make the bend into the nasopharynx.

The most patent nostril is prepped and the endotracheal tube is advanced until it makes

the bend into the nasopharynx in the manner described under nasotracheal intubation. If negotiating this bend is difficult, a well-lubricated fiberoptic scope can be placed through the tube and into the oropharynx to serve as a guide for the endotracheal tube. Once the tracheal tube is in the oropharynx, thorough oropharyngeal suctioning should be performed prior to introduction of the scope into the endotracheal tube. The fiberoptic scope is then advanced toward the larynx; the epiglottis and vocal cords are seen with little or no manipulation of the tip of the fiberoptic scope in 90% of patients. [72] As the scope is advanced, the cords are kept in view by frequent minor adjustments of the scope tip.

In the comatose or obtunded patient, the tongue and other soft tissue may obscure the view of the larynx; this can be alleviated by having an assistant pull the tongue forward or apply a chin or jaw lift. The scope is advanced through the larynx to the level of the midtrachea and the endotracheal tube is passed over the firmly held fiberoptic scope into the trachea (Fig. 2-20) (Figure Not Available) . It is helpful to remember that in adults the average distance from the naris to the epiglottis is 16 to 17 cm; if the scope has been advanced much beyond this distance and the glottis is still not seen, the scope is probably in the esophagus. [73] If the scope meets resistance at about this same level and only a pink blur is visible, the scope tip is probably in a piriform sinus; transillumination of the soft tissues may be present to confirm this as well as to indicate what corrective maneuvers are necessary.

The greatest impediment to successful fiberoptic intubation is the inability to visualize the larynx because blood or secretions have covered the optical element and cannot be removed. The best time to suction is *before* introducing the fiberoptic scope, actively suctioning the oropharynx just prior to scope insertion. Once the scope is in place, minor secretions can be suctioned through the fiberoptic suction port. Significant blood and secretions, however, are best removed by insufflation of oxygen through the suction port and out the tip of the scope, serving simultaneously to remove blood and secretions, defog the tip, and increase the inspired $O_2$ content. The set-up required for insufflation should be immediately available, if not already attached to the suction port prior to scope insertion. Once the scope has entered the trachea, difficulty may be encountered in advancing the endotracheal tube into the trachea. The tip of the tube most commonly catches on the right arytenoid cartilage or vocal cord; withdrawing the tube 2 cm, rotating it counterclockwise 90°, and readvancing the tube should result in successful tracheal intubation (see Fig. 2-13) (Figure Not Available) .

**Orotracheal approach.**

Oral fiberoptically guided intubation is indicated when contraindications to nasal intubation are present, the most common being severe midface trauma, or when the operator is more comfortable with this approach. The oral approach is more difficult than the nasal approach because the path of the scope is less defined by the surrounding soft tissue and the tip of the scope is more likely to impinge on the base of the tongue or vallecula. Attention to keeping the scope in the midline and elevating the soft tissue by pulling the tongue forward or applying the jaw lift will minimize this difficulty. Another disadvantage of the oral approach is that the oropharyngeal axis is not as well aligned with the laryngeal axis as in the nasal approach and thus requires more scope

manipulation to visualize the larynx.

The drawbacks of the oral approach can be minimized by using an oral intubating airway. This adjunct resembles an oropharyngeal airway but is longer and has a cylindrical passage through which the fiberoptic scope and tracheal tube are passed. The tip of this airway lies just cephalad to the epiglottis and assures midline positioning and a predictable place from which to advance the scope (Fig. 2-21) (Figure Not Available) .

The patient must be adequately anesthetized or obtunded to minimize the gag reflex. Topical anesthesia is achieved by spraying a 4 or 10% solution of lidocaine into the oropharynx. A degree of laryngeal and tracheal anesthesia may be achieved by a transoral spray using the laryngeal tracheal anesthetic (LTA) set. A well-lubricated fiberoptic scope, premounted with an endotracheal tube, is placed through the oral intubating airway and the trachea is fiberoptically intubated. The endotracheal tube is advanced over the scope into the trachea, frequently requiring the same counterclockwise manipulation as described with the nasal approach. After successful intubation, the intubating device can be left in place as a bite block, or it can be removed over the endotracheal tube after removal of the tube adapter. Some oral intubating airways can be removed from the mouth without disconnecting the endotracheal tube adapter.

### Complications

Complications of fiberoptic orotracheal intubation include prolonged intubation attempts and vomiting and laryngospasm in the underanesthetized patient. Oxygen saturation monitoring should alert the operator to hypoxemia from prolonged intubation attempts. The majority of complications seen with fiberoptically guided nasotracheal intubation are associated with the passage of the endotracheal tube through the nasopharynx. Epistaxis is most common, followed by other nasopharyngeal injuries seen with nasotracheal intubation in general. A rare but potentially significant complication may result if on blind advancement of the fiberoptic scope through the endotracheal tube, the tip of the scope inadvertently exits out through the distal side port (Murphy's eyes) as it is being advanced through the larynx into the trachea. [74] Attempts at passing the endotracheal tube through the larynx will fail because the tube tip, now extending off the midline, will catch on the laryngeal structures. This complication is avoided if the scope is introduced prior to tracheal tube placement.

### Summary

The primary advantage of fiberoptic intubation is its ability to negotiate difficult airway anatomy. It is noninvasive and well tolerated. Its major limitation in the emergency setting is lack of visibility in the presence of blood and secretions. The fiberoptic scope requires more practice than other methods of airway management; the first experience using the scope should not be in the setting of an emergency airway problem. Once familiarity and facility with the scope are acquired, fiberoptic intubation can be used early in the management of the difficult airway rather than as a last resort after repeated

failed attempts using conventional techniques.

## Retrograde Intubation

Retrograde orotracheal intubation is a technique of guided endotracheal intubation using a wire or catheter placed percutaneously through the cricothyroid membrane or high trachea and exiting through the mouth or nose. An endotracheal tube is then passed over this guide and advanced through the vocal cords into the trachea. Introduced by Butler and Cirillo in 1960, [75] the technique has undergone several recent modifications that have enhanced its value as a means of establishing a definitive airway when more conventional techniques have failed.

### Indications and Contraindications

Retrograde intubation is indicated when definitive airway control is required and less invasive methods have failed. Indications include trismus, ankylosis of the jaw or cervical spine, upper airway masses, unstable cervical spine injuries, and maxillofacial trauma. It can be used to convert transtracheal needle ventilation (see Chapter 4) into a definitive airway. It has been described in a 1-month-old with developmental abnormalities. [76] It is particularly helpful in the trauma patient with airway bleeding that prevents visualization of the glottis. A striking example of the efficacy of this technique is presented in an article by Barriot and Riou describing successful out-of-hospital retrograde intubation in a series of trauma patients in whom attempts at conventional intubation failed. [77]

Contraindications to this procedure include the ability to control the airway by less invasive means. The inability to open the mouth is another contraindication. A relative contraindication is the apneic patient who cannot be effectively ventilated using the bag-valve-mask; in this setting it is advisable to first establish transtracheal needle ventilation (see Chapter 4) before attempting retrograde intubation or to go directly to cricothyrotomy.

### Equipment

Needed materials include the following: (1) local anesthetic and skin preparation materials, (2) 18-ga needle, (3) 60 cm epidural catheter-needle combination or 80 cm (0.88 mm diameter) spring guide wire (J-tip preferred), (4) hemostat, (5) long forceps (e.g., Magill) for grasping wire in pharynx, (6) endotracheal tube of appropriate size, (7) syringe for tube cuff, and (8) materials for securing tube. A prepackaged alternative is the Cook Retrograde Intubation Set (Cook Critical Care, Bloomington, Ind), which also contains a sheath.

### Procedure

Three anatomic landmarks must be located by palpation: the hyoid bone, thyroid cartilage, and cricoid cartilage. The skin overlying the cricothyroid membrane is prepped and anesthetized. Next, the lower half of the cricothyroid membrane is punctured with a

needle directed slightly cephalad. The bevel should also face cephalad. Air is aspirated to confirm needle tip position within the lumen of the larynx (see also Chapter 4) . An alternative entry point is the high trachea, usually through the subcricoid space, using the same steps as described for the cricothyroid membrane.

The syringe is removed and the wire is then passed through the needle and advanced until it is seen in the patient's mouth, with the help of the laryngoscope, or until it exits out the nose. If the wire is found in the hypopharynx, it is grasped with the Magill forceps and drawn out through the mouth. The needle is removed from the neck and the end of the wire is secured at the puncture site with a hemostat. The oral end of the wire is then threaded in through the endotracheal tube side port--not the end of the tube--and advanced up the tube until it can be grasped by a second hemostat. Threading the wire through the side port allows the tube tip to protrude 1 cm beyond the point at which the wire enters the larynx. The wire is then pulled taut and moved back and forth to ensure that no slack remains.

The endotracheal tube is then advanced over the wire until resistance is met. This is the most critical point in the procedure; because this is a blind technique, it may be difficult to determine whether the tube has entered the trachea or is hung up on more proximal structures. If the endotracheal tube has successfully passed through the vocal cords and it is being restricted by the guide wire as it traverses the anterior laryngeal wall, one should feel some caudally directed tension on the wire at its laryngeal insertion point. If this does not occur, the tip of the endotracheal tube may be proximal to the vocal cords, either in the vallecula, the piriform sinus, or abutting the narrow anterior aspect of the vocal cords. If in doubt, pull the tube back 2 cm, rotate it 90° counterclockwise, and readvance the tube. This will usually result in successful passage through the larynx. [73] When satisfied that the tube has entered the trachea, the tube should be stabilized and the guide wire pulled out through the mouth. The tube is then advanced further into the trachea.

The classic method of retrograde intubation, as described above, has undergone modifications that facilitate the passage of the endotracheal tube through the glottis. A significant advance has been the addition of a plastic sheath that is passed antegrade over the wire until it meets resistance at the point at which the wire penetrates the laryngeal mucosa (Fig. 2-22) (Figure Not Available) . [78] This sheath needs to be stiff enough to effectively guide an endotracheal tube, yet small enough to easily pass through the vocal cords without impinging on supraglottic or glottic structures. Once the sheath comes to rest against the anterior laryngeal wall, the wire is withdrawn from the mouth and the sheath is advanced. With the sheath well within the trachea, the endotracheal tube is passed over the sheath. Any resistance that may be encountered at the arytenoids or vocal cords can usually be remedied by pulling the tube back 1 to 2 cm and rotating it counterclockwise 90°. One advantage of the antegrade sheath is that it lies freely in the larynx, allowing for a more posterior passage through the widest distance between the cords. The wire, however, pulls the endotracheal tube anteriorly toward the narrow commissure of the vocal cords and is more likely to result in impingement of the tube on the cords. Also, the use of the sheath permits unrestricted advancement of the endotracheal tube, whereas a wire entering the larynx 1.0 to 1.5 cm below the vocal cords prevents the tube from advancing more than this distance prior to

removal of the wire.

If no sheath is available, one should consider placing the needle inferiorly in the subcricoid space, thereby increasing the distance the endotracheal tube can be advanced before being stopped by the wire. [79] This will decrease the likelihood of dislodging the endotracheal tube tip when the guide wire is withdrawn.

Up to this point, blind retrograde intubation has been described. A further modification of the technique allows for visualization using a fiberoptic scope. [80] In addition to the scope, an extra long guide wire (e.g., 125 cm, 0.025 cm Teflon-coated J-wire) is also required. The procedure is the same as previously described up to the point at which the wire is withdrawn from the mouth. At that point, with a endotracheal tube mounted on a lubricated fiberoptic scope, the long guide wire is passed retrograde up through the end of the fiberoptic scope and out the suction port. The fiberoptic scope is then advanced over the guide wire and through the cords, coming to rest against the anterior laryngeal wall (Fig. 2-23) (Figure Not Available) . The wire is withdrawn from the suction port and the scope is advanced into the trachea. The endotracheal tube is then passed over the fiberoptic scope, and visualization guarantees correct endotracheal placement. The scope is then withdrawn and the lungs are auscultated.

### Complications

The complications of retrograde intubation are largely related to cricothyroid membrane puncture (see Chapter 4) . Hemorrhage is minimized by taking care to puncture the cricothyroid membrane in its lower half (to avoid the cricothyroid artery). Subcutaneous emphysema may occur, but it is of no clinical significance because no air is insufflated during this technique. A small incidence of soft tissue infection is reported with translaryngeal needle procedures, but this can be minimized by ensuring that the wire is withdrawn from the mouth rather than the neck.

The final complication, the failure to achieve intubation, has been mitigated by the addition of the antegrade sheath over the wire.

### Summary

Retrograde intubation is an underused technique for achieving endotracheal intubation in a patient who cannot be intubated by less aggressive means. It is more invasive than fiberoptic intubation but requires less skill. Whereas retrograde intubation usually takes several minutes to complete, [81] the patient can undergo bag-mask ventilation through much of the procedure. Recent modifications in the technique guarantee this method a prominent place in the management of the difficult airway, particularly when active bleeding compromises the airway.

## CHANGING TRACHEAL TUBES

The tracheal tube with a leaking cuff is a vexing problem, especially if the original intubation was difficult. A method of replacing the tube without losing control of the

tracheal lumen is preferred. This can be achieved by passing a guide down the defective tube, withdrawing the tube while leaving the guide in place, and introducing a new tube over the guide and into the trachea.

A number of different guides have been described (e.g., simple nasogastric tubes, 18 Fr Salem sump tubes [Table 2-5] , feeding tubes), but they are poor substitutes for a designated tube exchanger such as the TTX "tracheal tube exchanger" (Sheridan Catheter Corporation, Argyle, NY) or a similar commercially available device. The advantages of the designated tube exchanger are that it is stiff enough to prevent dislodgment when the endotracheal tube is introduced, it is ready to use without modification, it has a printed scale to aid in determining depth of placement, and if replacement is prolonged, the patient may be oxygenated using the exchanger and wall oxygen.

**Procedure**

Prior to the procedure, the patient is properly sedated or restrained. The patient is hyperventilated before placing the guide through the existing tube. The guide is lubricated and advanced into the defective tube so that it is well within the tracheal lumen (adults, 30 cm). While applying cricoid pressure (Sellick maneuver), the defective tube is withdrawn over the guide, and care is taken not to dislodge the guide when removing the tube. The replacement tube is then slid over the guide and is gently advanced into the trachea (Fig. 2-24) (Figure Not Available) . At this juncture, it may be helpful to perform a jaw thrust or chin lift to facilitate passage through the pharynx. Resistance may be encountered at the laryngeal inlet or vocal cords; if this occurs, withdraw the tube 1 to 2 cm, rotate it 90° counterclockwise, and readvance it. With the tube clearly in the trachea, remove the guide, inflate the cuff, and ventilate the patient. After correct placement has been verified, the new tube can be secured.

Complications are related to the time required to change the tube. A successfully performed procedure can be accomplished within 30 seconds. Laryngeal injury from forcing the guide or the tube is a possibility to consider when replacing a tube

## CONCLUSION

Airway management in the critically ill or injured patient with acute airway compromise is a most demanding task for the emergency physician. Mastery of oral and nasotracheal intubation and a facility with various guided intubation techniques, plus a competence with the surgical approaches, is

---

**TABLE 2-5** -- Procedure for Changing an Orotracheal Tube Using a Salem Sump Nasogastric Tube as a Guide

---

| | |
|---|---|
| 1. | Cut off the proximal 6 to 8-cm flared end of an 18 Fr Salem sump nasogastric tube. |
| 2. | Test the balloon or cuff of the new tracheal tube. An 8.0-mm tracheal tube should be used. Remove the proximal adapter from the new tracheal tube. |
| 3. | Sedate the patient and restrain the hands as necessary. Preoxygenate as much as possible. |
| 4. | Lubricate the entire length of the nasogastric tube with water-soluble (K-Y, Lubrifax) lubricant. |
| 5. | Advance the nasogastric tube as far as possible into the trachea through the existing tracheal tube. |
| 6. | Deflate the balloon of the existing tracheal tube and remove it. *Now only the nasogastric tube remains in the trachea, to be used as a guiding stylet.* |
| 7. | Thread the proximal end of the nasogastric tube through the distal end of the new tracheal tube. This is facilitated by the use of a hemostat. |
| 8. | Advance the new tracheal tube over the guide until the nasogastric tube exits through the proximal opening in the new tracheal tube. |
| 9. | Grasp the exiting nasogastric tube, have an assistant *lift the patient's jaw*, and advance the tracheal tube over the guide into the trachea. If resistance is encountered, rotate the tube 90° counterclockwise. |
| 10. | Remove the guide. |

| 11. | Replace the adapter on the new tracheal tube, inflate the cuff, and ventilate the patient. Confirm proper placement of the new tube. |

necessary to meet all emergency situations that might occur. Preparation (including mastery of technique), advance preparation of equipment, and experience in clinical decision-making are essential. Scenario visualization is one means of practicing the difficult decisions that will afford the patient the most expeditious and safest means of airway control available under the circumstances.

# Chapter 3 - Pharmacologic Adjuncts to Intubation

**Steven C. Dronen**

Endotracheal intubation in the acute care setting presents a challenge distinct from that associated with intubation of the fasted, premedicated patient in the operating room. The emergency department (ED) patient is frequently uncooperative and unstable and may have medical problems that are completely unknown to the treating physician. Often within a matter of minutes, the physician is expected to assess and control the airway, as well as to diagnose and manage other life-threatening problems.

In 1979, Taryle and colleagues reported that complications occurred in 24 of 43 patients intubated in a university hospital ED. They called for improved house officer training in endotracheal intubation, as well as "more liberal use of the procedures used in the operating room, such as sedation and muscle relaxation." [1] Since the report of Taryle and others, training programs in both critical care and emergency medicine have been greatly expanded, resulting in significant improvement in the expertise of physicians who provide acute airway management. Simultaneously, the use of established pharmacologic adjuncts to intubation previously available only in the operating room has increased. In addition, new drugs have been developed that are potent, rapid acting, and relatively safe, giving the physician greater ability to tailor therapy to specific clinical problems. [9] [10] Because of these developments, physicians now may not only concentrate on the manual skill of intubation, but also skillfully use drugs to achieve specific objectives. These objectives may include (1) immediate airway control necessitating induction of anesthesia and muscle relaxation; (2) provision of analgesia and sedation to the awake patient; and (3) minimization of intubation adverse effects, including systemic and intracranial hypertension.

This chapter reviews the pharmacology and use of the drugs that are currently available to facilitate intubation in the acute care setting.

## RAPID-SEQUENCE INDUCTION OVERVIEW

In the critically ill patient who may be hypoxic, hemodynamically unstable, agitated, uncooperative, and at risk of further deterioration, it is frequently necessary to gain immediate control of the airway. In recent years the technique of rapidly inducing anesthesia (rapid-sequence induction [RSI]) as a means of airway control has gained broad acceptance among emergency physicians. RSI as practiced in the ED is a modification of the process initially described in the anesthesia literature and used to minimize the risk of aspiration in patients with full stomachs who require anesthesia. There is also a subtle but significant modification of the intent of RSI as practiced in the ED. Whereas anesthesiologists have used RSI to intubate patients requiring anesthesia, emergency physicians commonly use RSI to induce anesthesia in patients requiring intubation.

As described by Stept and Safar, [11] RSI includes 13 steps, several of which are not practical or relevant to the ED setting. In the ED, RSI is begun by placing the patient on

100% oxygen, for at least 2 to 3, and ideally 5, minutes. The intent is to denitrogenize the lungs and build an oxygen reserve that will last several minutes should intubation prove to be difficult. Under optimal conditions, breathing 100% oxygen for 3 minutes has been demonstrated to maintain acceptable oxygen saturation for 8 minutes. [12] The same study demonstrated that 4 maximal breaths of 100% oxygen from a face mask maintained acceptable saturation for 6 minutes. Comparable results should not be expected in the ED setting because of differences in the underlying health and cooperation of the patient population. Therefore, preoxygenation should be maintained for the longest period practical prior to beginning intubation.

During the period of preoxygenation, the airway should be assessed to determine the likelihood of a difficult intubation while establishing an IV line, placing the patient on cardiac and pulse oximetry monitors and assembling all necessary equipment for oral intubation and potentially cricothyrotomy. A defasciculating dose of a nondepolarizing neuromuscular blocking agent is commonly recommended 2 to 3 minutes prior to administration of succinylcholine, although the advantages of this time-consuming step are generally overstated. General anesthesia is then rapidly induced with one of the agents discussed below, followed immediately by muscle paralysis with succinylcholine at a dose of 1.5 to 2.0 mg/kg. Cricoid pressure is applied by an assistant as consciousness is lost. After the onset of adequate relaxation, orotracheal intubation is performed, and correct tube placement is verified. Cricoid pressure can then be released and ventilation with 100% oxygen begun. Mask ventilation prior to intubation is unnecessary if adequate preoxygenation occurs and in fact should be avoided because of potential gastric distention and passive regurgitation. Mask ventilation should be used only if adequate oxygenation cannot be ensured and then should be performed gently in association with cricoid pressure. In the event of failure to obtain orotracheal intubation, cricothyrotomy generally should be performed. In some cases, bag-mask ventilation with cricoid pressure may temporize until a repeat orotracheal attempt or alternative approach is made. The protocol for RSI is described in Table 3-1 .

The two general types of drugs used most commonly as part of RSI protocols are anesthetic agents and neuromuscular blocking agents. These are discussed in greater detail below.

## ANESTHETIC AGENTS

A number of diverse drugs are routinely used in the ED to induce anesthesia prior to intubation. These include thiopental, methohexital, ketamine, etomidate, and propofol. Midazolam and fentanyl may also be used; these two agents are more commonly used at low doses as conscious sedation agents (see Analgesia and Sedation). The choice of a particular anesthetic agent depends to a great extent on the experience and training of the physician and to a

**TABLE 3-1** -- Rapid-Sequence Induction Protocol

1. Preoxygenate (denitrogenize) the lungs by providing 100% oxygen by mask. If ventilatory assistance is necessary, bag gently while applying cricoid pressure.

2. Assemble required equipment:

Bag-valve-mask connected to an oxygen delivery system

Suction with Yankauer tip

Endotracheal tube with intact cuff, stylette, syringe, tape

Laryngoscope and blades, in working order

Cricothyrotomy tray

3. Check to be sure that a functioning, secure IV line is in place.

4. Continuously monitor the cardiac rhythm and oxygen saturation.

5. Premedicate as appropriate:

*Fentanyl:* 2 to 3 mug/kg given at a rate of 1 to 2 mug/kg/min IV for analgesia in awake patients

| |
|---|
| *Atropine:* 0.01 mg/kg IV push for children or adolescents (minimum dose of 0.1 mg recommended) |
| *Lidocaine:* 1.5 to 2.0 mg/kg IV over 30 to 60 seconds |
| 6. Induce anesthesia with one of the following agents administered intravenously: thiopental, methohexital, fentanyl, ketamine, etomidate, or propofol. |
| 7. Give succinylcholine 1.5 mg/kg IV push (use 2.0 mg/kg for infants and small children). |
| 8. Apnea, jaw relaxation, and decreased resistance to bag/mask ventilations indicate that the patient is sufficiently relaxed to proceed with intubation. |
| 9. Perform endotracheal intubation. If unable to intubate during the first 20-second attempt, stop and ventilate the patient with the bag-mask for 30 to 60 seconds. Follow pulse oxymetry readings as a guide. |
| 10. Treat bradycardia occurring during intubation with atropine 0.5 mg IV push (smaller dose for children; see item 5). |
| 11. Once intubation is completed, inflate the cuff and confirm endotracheal tube placement by auscultating for bilateral breath sounds and checking pulse oxymetry and capnography readings. |
| 12. Release cricoid pressure and secure endotracheal tube. |

certain extent on institutional protocols governing use of these agents. Drugs commonly used and their doses are listed in Table 3-2 .

**Barbiturates: Thiopental and Methohexital**

The barbiturates, in particular thiopental, have been the traditional agents used for RSI in the operating room. These agents are used less often in the ED setting because of their

| TABLE 3-2 -- Recommended Anesthetic Doses for Rapid-Sequence Induction | |
| --- | --- |
| **Drug** * | **Dose** |
| Thiopental | 3-5 mg/kg IV |
| Methohexital | 1-3 mg/kg IV |
| Fentanyl | 5-15 mug/kg IV |
| Ketamine | 1-2 mg/kg IV |
| Etomidate | 0.3 mg/kg IV |
| Propofol | 2.0 mg/kg IV |

reputation as cardiorespiratory depressants. Of these two agents, methohexital is used more commonly in the ED because of its extremely rapid onset and short duration of action.

**Pharmacology**

Following IV injection, the ultrashort-acting barbiturates bind rapidly to plasma proteins, particularly albumin. Unbound barbiturate quickly accumulates in highly vascular

organs, reaching peak brain levels in as short a time as 50 seconds. The drugs then diffuse from the brain, ultimately reaching equilibrium between the intracerebral and plasma concentrations. Degradation occurs primarily in the liver, producing inactive metabolites that are excreted in the urine or gut, depending on the drug used. Single-pass hepatic clearance is substantially higher for methohexital than for thiopental, which accounts for the former drug's shorter duration of action. The period of anesthesia following a single IV dose of methohexital is 4 to 6 minutes, compared with 5 to 10 minutes for thiopental. [13] [14]

The barbiturates are central nervous system (CNS) depressants that are capable of producing mild sedation to deep coma. They do not block afferent sensory impulses to a significant extent and therefore should be used in conjunction with an analgesic agent such as fentanyl if a painful procedure is to be performed. However, it is common practice to intubate patients who have received only barbiturates. [14]

The advantages of barbiturates as adjuncts to intubation include their high potency, rapid onset, and short duration of action, traits they share with fentanyl and midazolam. The barbiturates are also known to reduce cerebral metabolism and oxygen consumption and, secondarily, cerebral blood flow and intracranial pressure (ICP). [15] [16] For this reason, thiopental is considered the agent of choice for anesthesia induction and maintenance in patients with elevated ICP. Some have stated that thiopental is the drug of choice to temporarily anesthetize the patient with a head injury before intubation. It has not been proved, however, that barbiturates exert a protective effect on the CNS when used for a short period of time during RSI. Moreover, their use in trauma patients may lead to systemic hypotension and impaired cerebral perfusion pressure that may offset the theoretic advantages of barbiturate therapy.

**Dose**

The recommended dose of thiopental is 3 to 5 mg/kg IV administered as a 2.5% solution over 60 seconds. Normal saline should be used as a diluent. Methohexital is given at 1 to 3 mg/kg IV over 30 to 60 seconds.

**Adverse Effects**

It has been stated that barbiturates are "fatally easy" to use. [14] This is an overstatement that reflects improper use of the drugs more than an inherent danger associated with their proper use. The most significant complication of barbiturate therapy is depression of the vasomotor center and myocardial contractility leading to significant hypotension. This may be particularly pronounced in the presence of hypovolemia or cardiovascular disease.

Barbiturates also depress the brainstem respiratory centers when given rapidly or in large doses. This effect may be accelerated by simultaneous treatment with opioids. Patients

with asthma or chronic bronchitis may experience bronchospasm. Laryngospasm may

occur in patients who were anesthetized lightly with barbiturates during manipulation of the upper airway. Laryngospasm usually responds to positive-pressure ventilation or paralysis with succinylcholine. In addition, the high pH of the barbiturate solution can cause tissue necrosis following extravascular administration and severe pain, vessel spasm, and thrombosis following intraarterial infusion.

## Etomidate

Etomidate is an ultrashort-acting nonbarbiturate hypnotic agent that has been used successfully as an anesthesia induction agent in Europe since the mid-1970s and in the United States since 1983. Only recently has it been used as an adjunct to intubation in the ED. A potentially significant benefit of etomidate in the emergency setting is its lack of cardiodepressant effects. [17] Although experience in this setting is limited, etomidate's potency, rapid onset, short duration of action, and minimal side effects suggest that it will become much more widely used.

### Pharmacology

Etomidate is a carboxylated imidazole that is both water and lipid soluble. The drug rapidly accumulates in vascular organs, reaching peak brain concentrations within 1 minute of IV infusion. [18] Sleep is produced within 1 arm-brain circulation time and lasts less than 10 minutes following a single bolus infusion. [19] Redistribution of the drug is quite rapid (distribution half-life, 2.6 minutes), which accounts for the short duration of action. Etomidate is rapidly hydrolyzed in the liver and plasma, forming an inactive metabolite excreted primarily in the urine. [18]

Etomidate acts on the CNS to stimulate gamma-aminobutyric acid receptors and depress the reticular activating system. After IV infusion, etomidate produces electroencephalographic changes similar to those produced by barbiturates as patients pass rapidly through light to deep levels of surgical anesthesia. Because etomidate has no analgesic activity, [18] it should be used in conjunction with an analgesic such as fentanyl when painful conditions are being treated. Etomidate decreases cerebral oxygen consumption, cerebral blood flow, and ICP but appears to have minimal effects on cerebral perfusion pressure. [20]

### Dose

The recommended dose is 0.3 mg/kg IV. There is virtually no accumulation of the drug, and anesthesia may be maintained through repeated or continuous dosing. [21]

### Adverse Effects

The most common side effects of etomidate are nausea and vomiting, pain on injection, and myoclonic jerks. [22] Pain on injection occurs in up to two thirds of cases. Use of a large vein, simultaneous saline infusion, and opioid premedication are reported to reduce this side effect. [23] Myoclonic activity has been reported in about one third of cases and is believed to be caused by disinhibition of subcortical activity rather than

CNS stimulation. [18]

**Ketamine**

**Pharmacology**

Unique among anesthetic agents currently in use, ketamine produces a dissociative anesthesia characterized by excellent analgesia and amnesia despite the appearance of wakefulness. As a drug that is potent and relatively safe and possesses a rapid onset and brief duration of action, ketamine fits the profile of a drug that could be used effectively to facilitate intubation. It does, however, possess a number of pharmacologic properties that limit its use to selected circumstances.

Ketamine is a water- and lipid-soluble drug with rapid penetration into the CNS. Like the barbiturates, ketamine accumulates rapidly in highly vascular organs and then undergoes redistribution. The half-life of redistribution from plasma to peripheral tissues is 7 to 11 minutes, and the half-life of elimination is 2 to 3 hours. Degradation occurs primarily in the liver. [24]

Unlike other anesthetic agents that depress the reticular activating system, ketamine acts by interrupting association pathways between the thalamocortical and limbic systems. Characteristically, the eyes remain open, and patients exhibit spontaneous, although not purposeful, movements. Increases in blood pressure, heart rate, cardiac output, and myocardial oxygen consumption are seen--effects that are most likely mediated through the CNS. In vitro studies indicate that ketamine is a myocardial depressant, but the CNS-mediated pressor effects generally mask the direct cardiac effects. [25] [26] Respirations are initially rapid and shallow after ketamine administration, but they soon return to normal.

Other features of ketamine anesthesia include increased skeletal muscle tone, preservation of laryngeal and pharyngeal reflexes, hypersalivation, and relaxation of bronchial smooth muscle. ICP is increased, most likely as a consequence of increased cerebral blood flow. [24]

Ketamine has been recommended for anesthesia induction in children because of its relative safety and infrequency of postanesthesia emergence reactions in this group. There is no evidence, however, that it offers any advantage over commonly used agents. Ketamine also has been recommended for the unstable critically ill patient, because it does not depress the cardiovascular system. This recommendation is too vague to be useful to the clinician, and it ignores the fact that ketamine is potentially harmful in patients with cardiac ischemia (because it can increase myocardial oxygen consumption) or acute intracranial pathology (because it can increase ICP). Ketamine may be useful during hemorrhagic shock because of its cardiostimulatory effect. Its administration to patients in shock has been reported to cause a fall in blood pressure only when the shock state has been prolonged. [29] [30]

The most promising use of ketamine as an intubation adjunct has been in the setting of

acute bronchospastic disease. Ketamine relaxes bronchial smooth muscle either directly, through the enhancement of sympathomimetic effects, or through the inhibition of vagal effects. Ketamine also increases bronchial secretions, which may decrease the incidence of mucus plugging commonly reported in autopsies of asthmatic patients. [31] Clinical studies have demonstrated a reduction in airway resistance and an increase in pulmonary compliance that occur within minutes of ketamine administration. L'Hommedieu and Arens [8] reported

prompt improvement in respiratory acidosis in 5 asthmatics intubated with ketamine and succinylcholine.

**Dose**

The recommended dose of ketamine before intubation is 1 to 2 mg/kg administered IV over 1 minute. Anesthesia occurs within 1 minute of completing the infusion and lasts approximately 5 minutes. A small dose (0.5 to 1.0 mg/kg) may be given 5 minutes after the initial dose if there is a need to maintain anesthesia. The simultaneous administration of succinylcholine and midazolam is recommended to provide adequate muscle relaxation and to decrease the incidence of postanesthesia emergence reactions.

**Adverse Effects**

A side effect that has greatly limited the use of ketamine is its tendency to produce postanesthesia emergence reactions, a characteristic that it has in common with the structurally similar drug phencyclidine. The reactions may be marked and distressing to the patient; symptoms include floating sensations, dizziness, blurred vision, out-of-body experiences, and vivid dreams or nightmares. The reported incidence of these reactions varies from 5 to 30%. They are less common in children than in adults.

Of the drugs that have been evaluated for their ability to suppress postanesthesia emergence reactions, the benzodiazepines show the most promise. Both diazepam and lorazepam are useful, but the latter is more effective, most likely owing to its enhanced amnestic effect. Midazolam has not been evaluated as thoroughly as have the other benzodiazepines, but it has potent amnestic effects and offers the advantage of a short duration of action. White [40] reported a 55% incidence of postemergence dreaming in patients receiving ketamine and complete suppression of dreaming with the addition of midazolam. Evidence also suggests that midazolam may inhibit the cardiostimulatory effects of ketamine.

Although ketamine produces excellent analgesia and is relatively safe, its use as an agent to facilitate intubation is somewhat limited. The widely held belief that aspiration does not occur with ketamine because of preservation of pharyngeal and laryngeal reflexes is incorrect. Moreover, ketamine does not relax skeletal muscle. The production of desired intubation conditions often requires the simultaneous administration of a paralytic agent, thereby removing any upper airway reflexes.

**Propofol**

Emergency department experience with propofol is limited, and it is uncertain whether it will have a significant role as an adjunct to intubation in this setting.

**Pharmacology**

Propofol is an alkylphenol sedative-hypnotic recently introduced for induction and maintenance of general anesthesia. The drug has no analgesic activity, but it does have an amnestic effect. It produces dose-dependent depression of consciousness ranging from light sedation to coma. Propofol is a highly lipophilic, water-insoluble compound that undergoes rapid uptake by vascular tissues, including the brain, followed soon afterward by redistribution to the muscle and fat. The drug is metabolized by the liver and excreted in the urine.

**Dose**

Following an induction dose of 2 mg/kg IV, hypnosis occurs within 1 minute and lasts for 5 to 10 minutes. A smaller dose (1.0 to 1.5 mg/kg) is recommended in the elderly and when simultaneously administering other CNS depressants. Because propofol has a short duration of action and patients rapidly regain consciousness, repeat bolusing is not a practical way to maintain a desired level of anesthesia or sedation.  A slow drip infusion of 3 to 5 mg/kg/hour titrated to effect is the preferred technique. Conscious sedation may be achieved using a drip infusion beginning at 6 mg/kg/hour and decreasing the rate as the desired level of sedation is obtained.

**Adverse Effects**

Side effects of propofol include direct myocardial depression causing a moderate fall in blood pressure, particularly in the elderly, in hypovolemic patients, and when administered simultaneously with opioids. Propofol reduces cerebral blood flow and may cause mild CNS excitation activity (e.g., myoclonus, tremors, hiccups) during anesthesia induction. Pain on injection occurs commonly, even when the drug is infused slowly.

# NEUROMUSCULAR BLOCKING AGENTS

## Overview

Neuromuscular blocking agents (NMBs) are the standard agents used to achieve muscle relaxation for intubation, because they permit complete airway control and greatly simplify visualization of the vocal cords. This is particularly important when intubation must be performed quickly under less than ideal circumstances. NMBs are used routinely for RSI, as well as in conjunction with sedatives during "awake" intubation. Sedatives may be used to provide some muscle relaxation, but this requires that they be administered rapidly and in large doses, risking depression of the

cardiovascular system. The combination of a paralytic agent and a sedative or an analgesic agent is generally superior to the use of either agent alone.

The only absolute contraindication to the use of NMBs is the inability to manage the airway once the patient becomes apneic. Although not absolutely contraindicated, it is relatively inhumane to paralyze and intubate an alert patient. A sedative or an analgesic agent should always be administered simultaneously if the patient is able to perceive pain.

Controversy surrounds the use of NMBs to facilitate intubation in the patient who may have a cervical spine injury. Despite claims to the contrary, there is no evidence that orotracheal intubation performed during in-line stabilization, with or without paralysis, is dangerous. Cadaver studies purporting to demonstrate the dangers inherent in this practice simply do not simulate the condition of a living patient accurately. [51] Conversely, no studies prove conclusively that orotracheal intubation following the use of NMBs is a safe practice, but it has been performed for a number of years in operating rooms without reported detrimental effects, even in patients with unstable cervical spine fractures. [52] [53]

NMBs are classified as either depolarizing or nondepolarizing. Depolarizing agents mimic the action of acetylcholine

(ACh), producing a sustained depolarization of the neuromuscular junction during which muscle contraction cannot occur. Nondepolarizing agents competitively block the action of acetylcholine at the neuromuscular junction and prevent depolarization. NMBs in common use and their dosages, onset, and duration of action are listed in Table 3-3 .

## Depolarizing Agents

### Succinylcholine

**Pharmacology.**

The standard depolarizing agent currently in use is succinylcholine, which was introduced in 1952. It has a chemical structure similar to that of acetylcholine and is therefore able to depolarize the postjunctional neuromuscular membrane. Administration is followed by a brief period of muscle fasciculation that corresponds to the initial membrane depolarization. Unlike acetylcholine, which is released in minute amounts and hydrolyzed in milliseconds, succinylcholine requires several minutes for significant hydrolysis to occur. During this time, the neuromuscular membrane remains depolarized, but the muscles relax and will not contract until the neuromuscular end plate and adjacent sarcoplasmic reticulum return to the resting state and are again depolarized. Relaxation proceeds from the small, distal, rapidly moving muscles to the proximal, slowly moving muscles. The diaphragm is one of the last muscles to relax. [54]

Succinylcholine is rapidly hydrolyzed in the serum by the enzyme pseudocholinesterase. Only a small amount ever reaches the neuromuscular junction,

and that portion is quickly drawn back into the serum by a concentration gradient produced by serum clearance. The duration of action of a single dose is 3 to 5 minutes. Relaxation may be maintained by repeated IV injections or a constant infusion. Prolonged or repeated use of the drug, however, may enhance its effects at either the vagal or sympathetic ganglia. Vagal stimulation may result in bradycardia and hypotension, as well as other muscarinic effects. These effects may be seen even at normal doses, particularly in children. [55] For this reason atropine pretreatment is recommended in all children and in adults receiving multiple doses. [56] Prolonged neuromuscular blockade is uncommon but may occur in patients with reduced pseudocholinesterase levels.

Repeat dosing may also produce desensitization blockade in which the neuromuscular membrane returns to the resting state and becomes resistant to further depolarization and succinylcholine.  Clinically this is indicated by an unsustained contraction in response to a tetanic stimulus and response to a test dose of edrophonium. [59] In general,

| | TABLE 3-3 -- Commonly Used Neuromuscular Blocking Agents | | |
|---|---|---|---|
| **Agent** | **Dose (mg/kg)** | **Onset (min)** | **Duration (min)** |
| Succinylcholine | 1.5 | 1 | 3-5 |
| Pancuronium | 0.1 | 2-5 | 40-60 |
| Vecuronium | 0.1 | 3 | 30-35 |
| | 0.25 | 1 | 60-120 |
| Atracurium | 0.5 | 3 | 25-35 |
| Mivacurium | 0.15 | 2-3 | 15-20 |

| | | | |
|---|---|---|---|
| Rocuronium | 1.0 | 1-1.5 | 30-110 |

there is little need for repeated doses of succinylcholine. If paralysis in excess of 3 to 5 minutes is desired, agents such as vecuronium or pancuronium should be used.

**Dose.**

The recommended dose of succinylcholine is 1.0 to 1.5 mg/kg given IV. It is better to err on the side of too large a dose, thereby guaranteeing complete relaxation and avoiding the need for repeat dosing.

**Adverse Effects.**

There are a number of potential adverse effects of succinylcholine use. These include muscle fasciculations and their side effects, hyperkalemia, stimulation of autonomic ganglia, malignant hyperthermia, prolonged apnea, histamine release, and elevation of ICP.

As noted previously, muscle fasciculations accompany the initial depolarization of the neuromuscular membrane. They may be prevented by preadministration of a subparalytic dose (0.01 mg/kg) of pancuronium. Fasciculations are most prominent in muscular adolescents but are uncommon in children. Their most frequent side effect is deep, aching muscle pain that may last for several days. [60] Fasciculations of the abdominal wall may elevate intragastric pressure and cause regurgitation of stomach contents. This is an uncommon complication that most often follows overzealous bag-mask ventilation before intubation. Distention of the stomach with air and failure to perform the Sellick maneuver (i.e., firm cricoid pressure to occlude the esophagus during airway management procedures) are more likely to cause vomiting than are muscle fasciculations alone. It is also important to note that oropharyngeal manipulation of the nonparalyzed patient is far more likely to cause vomiting than are succinylcholine-induced fasciculations.

Other reported but distinctly uncommon side effects of muscle fasciculations include elevations of intraocular pressure and skeletal fractures or dislocations. The clinical significance of a transient rise in intraocular pressure in a patient with a penetrating eye injury is unknown. There has never been a reported case of vitreous expulsion occurring during rapid-sequence intubation with succinylcholine, despite its widespread use in open eye surgery. [61] However, paralysis will prevent spontaneous patient motor activity such as coughing or gagging, both of which are associated with a greater risk of vitreous expulsion. Although it may be prudent to use a nondepolarizing agent in patients with penetrating eye injuries, a necessary intubation using succinylcholine should never be delayed or avoided because of this theoretical concern. [62]

The precise mechanism by which succinylcholine causes hyperkalemia is unknown, but it is thought to occur secondary to the asynchronous depolarization of muscle cells and resultant cellular injury. The elevation is typically less than 0.5 mEq/L. [63] In certain pathologic states the hyperkalemic response may be as much has 5.0 mEq/L. These conditions include late severe burns, [64] major muscle trauma, [65] and upper motor neuron disease. These large elevations occur only in patients who have had significant tissue injury or muscle denervation for several days or weeks before succinylcholine use. Succinylcholine is not contraindicated in the acute initial management of these patients.

Malignant hyperthermia is a rare complication with an autosomal dominant inheritance pattern. It occurs in approximately 1 in 15,000 children and 1 in 50,000 adults. [68] The clinical syndrome consists of high fever, tachypnea, tachycardia, cardiac arrhythmias, hypoxia, acidosis, myoglobinuria, and impaired coagulation. Muscle spasm rather than

relaxation is frequently seen. [69] Treatment includes aggressive cooling measures (see Chapter 72) , volume replacement, and correction of hypoxia and acid-base and electrolyte abnormalities. Dantrolene sodium, a direct-acting skeletal muscle relaxant, has been shown to be effective in reducing the muscle hypermetabolism that causes the fever. [70]

An associated abnormal response to succinylcholine is isolated masseter spasm. [71] Barlow and Isaacs reported two cases in which masseter spasm was the first abnormality noted in fatal episodes of malignant hyperthermia. [72] Masseter spasm may be more common in patients with neuromuscular disorders such as myotonia congenita.

Prolonged apnea may occur because of decreased pseudocholinesterase levels (e.g., in hepatic disease, anemia, renal failure, pregnancy, advanced age, bronchogenic carcinoma, or connective tissue disorders) or, more commonly, because of the inheritance of an atypical pseudocholinesterase present in about 0.03% of the population. This atypical enzyme has both a decreased affinity for the succinylcholine molecule and a decreased ability to hydrolyze it. The period of apnea is therefore increased from 3 to 5 minutes to up to several hours. Patients with markedly decreased levels of normal cholinesterase experience only a two- to three-fold increase in the duration of apnea. [73] Patients with cocaine intoxication may experience prolonged muscle relaxation if given succinylcholine, because cocaine is competitively metabolized by the cholinesterases.

The magnitude and significance of the increase in ICP that occurs with succinylcholine use remain controversial. [74] [75] [76] [77] [78] Increases in the range of 5 to 10 mm Hg have been reported by several investigators, but other researchers have shown no increase, nor is there evidence of neurologic deterioration associated with these transient elevations in ICP. Mechanisms that have been proposed to explain the elevated ICP include (1) a direct effect of fasciculations, (2) an increase in cortical electrical activity with a resultant increase in cerebral blood flow and blood volume, and (3) sympathetic postganglionic stimulation. Minton and colleagues have demonstrated that pretreatment with vecuronium (0.14 mg/kg) reduces the rise in ICP following succinylcholine

administration from mean values of 5 mm Hg to 1 mm Hg. [79] It has been postulated that nondepolarizing blockade prevents muscle spindle firing and the increase in cortical activity that may lead to increased ICP. Pretreatment with a nondepolarizing agent may not be practical when intubation must be performed rapidly; furthermore, the dose that has been shown to be effective is itself a paralyzing dose and would obviate the need for succinylcholine.

At present, questions concerning the safety of succinylcholine in the setting of acute intracranial pathology do not have clear answers. The drug has been used widely and successfully in this setting, and its continued use is supported. The eminent risk of airway compromise without the use of a depolarizing agent must always be weighed against the rare harmful effects mentioned.

## Nondepolarizing Agents

Nondepolarizing agents act in a competitive manner to block the effects of acetylcholine at the neuromuscular junction. Drugs in this class include pancuronium, atracurium, vecuronium, mivacurium, and *d*-tubocurarine. These drugs, particularly the intermediate-acting agents vecuronium and atracurium, have fewer side effects than succinylcholine and have the potential for reversal. However, they generally have longer onset and duration of action than succinylcholine, making them less attractive choices for rapid intubation. *In most instances, succinylcholine remains the agent of choice to facilitate emergency intubation,* and nondepolarizing agents are indicated to maintain paralysis after intubation. Of note, a new nondepolarizing agent, rocuronium, has an onset of action within 1 to 1.5 minutes, which may permit its use for rapid-sequence intubation when succinylcholine is contraindicated.

Because nondepolarizing agents act competitively, their effects may be reversed by increasing the concentration of acetylcholine. Cholinesterase inhibitors such as neostigmine or edrophonium may be used, but not until some spontaneous signs of reversal are seen. Thus, the concept of reversal is of limited clinical importance. When reversal is required, neostigmine 0.02 to 0.04 mg/kg is given by slow IV push. Additional doses of 0.01 to 0.02 mg/kg may be given in 5 minutes if reversal is incomplete, but the total dose should not exceed 5 mg in the adult. Atropine 0.01 mg/kg (with a *minimum* dose of 0.1 mg for adults) should be given concurrently with neostigmine to block its cholinergic effects. [80] [81] [82]

Of the nondepolarizing agents, pancuronium has been used the most widely, but its comparatively slow onset of action, long half-life, and greater incidence of side effects make it less than ideal for ED use. The recently introduced agents vecuronium and atracurium are preferable in most instances.

### Pancuronium

Pancuronium is an aminosteroid derivative that is primarily excreted in the urine within 1 hour of IV administration. [82] Classified as a long-acting agent, its onset and duration of

action are dose related.

Following the recommended 0.1 mg/kg IV dose, paralysis occurs within 2 to 5 minutes and lasts approximately 60 minutes. Paralysis may be maintained safely by repeated bolus or drip infusion. Because the effects of the drug are cumulative, repeating the original dose significantly lengthens the duration of paralysis.

**Adverse Effects.**

Relatively few adverse effects are associated with the use of pancuronium. Many patients experience an increase in heart rate, blood pressure, and cardiac output because of the vagolytic effect of the drug. Ventricular tachycardia and severe hypertension have been reported but are quite rare. Pancuronium may cause histamine release that results in bronchospasm or anaphylactic reactions. [85] Prolonged paralysis may also occur, primarily in patients with myasthenia gravis or with significant impairment of renal function.

**Vecuronium, Atracurium, Mivacurium, and Rocuronium**

Vecuronium and atracurium are intermediate-acting agents with an onset of action of about 3 minutes and a duration of action of 30 minutes. Mivacurium has an onset of action of 2 to 3 minutes and a duration of action of 15 to 20 minutes. These drugs represent significant advances over pancuronium in that they have minimal cardiovascular effects, cause little histamine release, and lack cumulative effects. [86]

**Dose.**

The recommended doses of vecuronium, atracurium,

mivacurium, and rocuronium are listed in Table 3-3 . Use of a larger than recommended dose will hasten the onset of action and greatly prolong the period of paralysis. For example, vecuronium at a dose of 0.25 mg/kg IV will cause paralysis in as little as 1 minute, but the period of paralysis will last 1 to 3 hours.  Because a rapid onset of action comparable to succinylcholine is achieved at high doses of intermediate-acting agents, they may be used as the sole agents to facilitate intubation, particularly if a long period of paralysis is desired after intubation. Similarly, rocuronium produces paralysis sufficiently rapidly to be used for rapid-sequence intubation. The duration of paralysis seems related to the dosing: a mean of 45 minutes is achieved with 0.6 mg/kg, and a mean of 85 minutes with 1.2 mg/kg. [89] However, the use of succinylcholine prior to intubation and an intermediate-acting agent at a normal dose after intubation provides rapid intubating conditions and excellent control over the duration of paralysis.

Paralysis induced by vecuronium or atracurium may be maintained by repeat bolus or drip infusion. Unlike both pancuronium and succinylcholine, there are no side effects specifically related to repeated dosing in the emergency department. A repeated dose of

0.01 to 0.02 mg/kg of vecuronium will extend the period of paralysis 12 to 15 minutes.

# ANALGESIA AND SEDATION

## Overview

An alternative to the induction of anesthesia in patients requiring intubation is the use of anesthetic and sedative agents in the conscious patient. Laryngoscopy in the awake patient has been likened to the "mouth being held open with a wrench." [90] The upper airway is richly innervated by sensory branches of the fifth, seventh, ninth, and tenth cranial nerves. In addition to pain fibers, there are stretch receptors that stimulate coughing and gagging reflexes with even minor airway manipulation. It is therefore essential that adequate analgesia be provided before intubation in all but the most critical circumstances. Treatment options include topical application of anesthetic agents to the pharyngeal and tracheal mucosa and IV infusion of analgesic or sedative agents.

## Local Anesthesia

Local or topical anesthesia techniques may be used in patients who are awake, either in place of or as a supplement to IV analgesia or sedation. They are particularly useful as adjuncts to nasotracheal intubation but do not generally provide the degree of analgesia or relaxation desirable for orotracheal intubation. In addition, it is time consuming to achieve good topical anesthesia, which may limit the usefulness of these techniques in emergency situations.

Topical anesthesia may be achieved by direct application using laryngoscopy, by cricothyroid membrane puncture, or by inhalation of a nebulized anesthetic.

### Direct Application Using Laryngoscopy

Achieving anesthesia of the oral and pharyngeal mucosa is a relatively simple procedure using commonly available agents such as 4% lidocaine or benzocaine-tetracaine-butamben-benzalkonium (Cetacaine). Achieving anesthesia of the hypopharynx is more difficult, because optimal results require application of the anesthetic to the epiglottis and vocal cords under direct vision.

This procedure is begun by spraying the tongue and pharynx with a topical agent. After allowing at least 2 to 3 minutes to permit numbing of the tongue and pharynx, the epiglottis and vocal cords are visualized using a laryngoscope and are sprayed directly with the anesthetic agent. Even if laryngoscopy is not used to facilitate this procedure, it is at best an unpleasant experience. It is also time consuming because of the inherent delay associated with mucosal absorption of an anesthetic agent. An alternative is percutaneous injection of an anesthetic agent into the trachea at the level of the cricothyroid membrane. [91] [92]

**Cricothyroid Membrane Puncture**

The cricothyroid membrane is identified in the trapezoidal space between the cricoid and thyroid cartilages. After appropriate skin preparation with an alcohol or povidone-iodine (Betadine) swab, the overlying tissue and membrane are punctured with a 22-ga needle in the midline and just above the superior border of the cricoid cartilage. Care should be taken to maintain the needle in the midline at all times to avoid injury to the recurrent laryngeal nerves. The needle should be advanced until air can be aspirated, indicating placement of the tip in the trachea. A volume of 2 mL of 4% lidocaine is then injected rapidly. Alternatively, 3 to 4 mL of 1% or 2% lidocaine, as used for local anesthesia, may be injected if the 4% concentration is not available. Typically this will precipitate a cough, which adequately distributes the anesthetic over the upper trachea, vocal cords, and epiglottis (see Chapters 4 and 5) .

**Nebulized Anesthesia**

This simple and painless technique can be used to facilitate awake intubation when the patient's condition is stable enough to permit a several-minute delay. [93] The anesthetic is delivered using a standard nebulizer and face mask connected to an oxygen source that delivers 4 to 8 L/min. A volume of 4 mL of a 4% solution is nebulized over about 5 minutes. Bourke and colleagues reported achieving consistently good topical anesthesia using this technique, although their patients were often premedicated with opioids, sedatives, or both. [94]

## Intravenous Analgesia and Sedation

The IV infusion of analgesic or sedative agents either alone or in combination is an excellent means of facilitating relatively painless intubation. In recent years a number of drugs have been released that are characterized by high potency, rapid onset of action, short half-life, and minimal potential for cardiorespiratory depression. Depending on the clinical situation encountered, the doses of these drugs may be titrated to produce alterations of consciousness ranging from very light sedation to complete loss of consciousness. To facilitate orotracheal intubation, these drugs are frequently used in conjunction with succinylcholine, thus producing a state of complete muscle relaxation, good analgesia, reduced anxiety, and loss of recall for the event.

The most commonly used classes of drugs for sedation prior to intubation are opioids and benzodiazepines. Anesthetic

agents previously discussed, in particular the barbiturates, may also be used as sedatives, although in lower doses than required for RSI.

**Opioids (Fentanyl)**

Although any of several opioids administered IV could be used to induce conscious sedation, only fentanyl will be discussed because it possesses significant advantages

over other opioid agents.

**Pharmacology.**

Fentanyl is a synthetic opioid related to the phenylpiperidine family. Since its introduction in 1968, fentanyl has been used widely in a variety of settings, often replacing meperidine as the agent of choice for rapid short-term analgesia.  Its favorable pharmacologic properties include a highly lipophilic nature, rapid serum clearance, high potency, and minimal histamine release.  Fentanyl crosses the blood-brain barrier rapidly, producing analgesia in as little as 1½ minutes. Serum levels decline rapidly from peak concentrations because of extensive tissue uptake. [ Unlike with morphine, the brain concentration of the drug falls in conjunction with the serum level. The duration of analgesic action is 30 to 40 minutes, although at high doses a second peak of activity may be seen several hours later because of the release of the bound drug from tissue stores. Fentanyl is about 50 to 100 times as potent as morphine sulfate. [106] This unique combination of potency and short half-life permits the administration of numerous small doses that can be titrated to the desired clinical effect. Similarly to other opioids, fentanyl is competitively reversed with naloxone or nalmefene.

**Dose.**

The relative safety of fentanyl permits considerable latitude in dosing. When used as a primary anesthetic agent for major surgical procedures, doses ranging from 50 to 100 mug/kg produce minimal side effects. [107] Comparatively tiny doses produce sedation, and 3 to 5 mug/kg, given at a rate of 1 to 2 mug/kg/min, is generally an effective analgesic dose. More rapid administration will cause greater depression of the level of consciousness. Mostert and coworkers reported successful awake intubation in 99 of 103 patients who were administered an average dose of 3.7 mug/kg. [100] Most of these patients were able to follow commands, and many recalled the events surrounding the intubation. A small percentage could not be intubated even after receiving 500 mug of fentanyl.

Larger doses, perhaps up to 25 mug/kg, may be needed to produce ideal intubating conditions, although if given rapidly, 10 mug/kg is usually adequate. However, even this lower dose is more likely to produce anesthesia than sedation and it may cause a longer period of unresponsiveness than is desirable. It is preferable to use a low dose of fentanyl (2 to 3 mug/kg) for analgesia combined with a paralytic agent (e.g., succinylcholine) to produce adequate muscle relaxation and a sedative (e.g., midazolam) to reduce anxiety and produce amnesia for the event.

**Adverse Effects.**

Unlike other opioids, fentanyl causes little or no histamine release, and its use is seldom associated with emesis or hypotension. It is probably the safest opioid to use in the hypovolemic patient. Fentanyl also has significantly less emetic effects than other opioids. Adverse effects that have been reported with fentanyl are few and primarily follow the rapid IV infusion of very large doses. Like other opioids, fentanyl may cause

rigidity of the skeletal musculature, including the chest wall and diaphragm. Typically this occurs with doses in excess of 15 mug/kg, but it has also been reported with doses as low as 10 mug/kg. [100] [108] The muscular rigidity may be prevented or treated with standard doses of succinylcholine or naloxone. [109] Grand mal seizures have also been reported but are very uncommon. Chudnofsky and colleagues [7] reported a complication rate of less than 1% in 841 emergency department patients treated with fentanyl. The most common complication was respiratory depression, and it generally occurred when fentanyl was given in combination with other CNS depressants.

**Benzodiazepines (Midazolam)**

**Pharmacology.**

The benzodiazepines are a widely used class of drugs characterized by anxiolytic, hypnotic, sedative, anticonvulsant, muscle relaxant, and amnestic effects. Several of these properties make the benzodiazepines ideal adjuvant agents for intubation, particularly when used in combination with opioids. It is important to remember that benzodiazepines do not have analgesic effects. Although they may produce excellent sedation and impair the patient's memory of an unpleasant experience, they will not prevent the pain associated with intubation. Diazepam has been used widely to facilitate intubation, but its use has been supplanted in recent years. Diazepam has a variable onset of action and a long elimination half-life, and it causes significant infusion site pain and frequently phlebitis when given intravenously.

Midazolam has, to a great extent, replaced diazepam as a preoperative sedative agent. Midazolam is also used widely as an anesthesia induction agent, even in high-risk elderly and cardiac patients. ] Compared with diazepam, the primary advantages of midazolam include a two-fold increase in potency, a shorter half-life, and a lessened potential for cardiorespiratory depression. Midazolam possesses a unique imidazole ring that is stable and water soluble in an acid medium but highly lipophilic at physiologic pH.

Because it does not require suspension in propylene glycol, midazolam is not a tissue irritant. It causes minimal pain on injection, is rarely associated with phlebitis, and can be given intramuscularly when a very rapid onset of action is not required. The highly lipophilic character of the drug permits rapid accumulation in the CNS with onset of sedation in as little as 1 to 2 minutes. Rapid penetration into fatty tissue coupled with extensive binding to plasma proteins causes a prompt fall in serum levels after IV administration. This may account for the paucity of side effects outside the CNS. The half-life of elimination is 1 to 4 hours and is dependent on release of the drug from adipose tissue and protein-binding sites. The period of sedation following a single IV dose is considerably shorter. Emergence from a 0.15 mg/kg dose occurs in 15 to 20 minutes. [118]

Clinical experience using midazolam for conscious sedation before the performance of surgical and dental procedures or as an adjunctive agent for the induction of anesthesia is considerable. Baker and Gordon reported the use of midazolam to achieve conscious sedation in 400 ambulatory surgery patients. [114] Used in combination with either

fentanyl or ketamine, midazolam was considered to be both effective and safe.

**Dose.**

The recommended dose for conscious sedation with midazolam is 0.05 to 0.1 mg/kg given in 1-mg boluses and not exceeding 2.5 mg over 2 minutes. Doses up to 0.1 mg/kg are often needed to produce good conditions for intubation. All patients receiving midazolam should be monitored

closely, and skilled personnel prepared to manage the airway should be present.

**Adverse Effects.**

Although midazolam was initially touted to be free of cardiorespiratory side effects, recent experience suggests that the potential adverse effects of midazolam are quite similar to those of other benzodiazepines. A small increase in heart rate is seen frequently, as is a small decrease in systolic blood pressure. [119] Changes in blood pressure may be exaggerated in the presence of hypovolemia. [120] Cardiac index and coronary artery blood flow are generally not affected. Respiratory depression may occur even at standard doses but most often follows rapid administration of an excessive dose. Respiratory depression is also more likely to occur in debilitated or elderly patients and in those simultaneously receiving opioids. Reports of fatalities soon after midazolam's introduction in the United States prompted changes in the recommendations for its use. These included lowering of the dosage schedule, reduction of the speed of administration, and careful patient monitoring during administration. [121] The effects of midazolam are rapidly reversed by the administration of the benzodiazepine antagonist flumazenil.

Limited information is available on the use of midazolam to facilitate ED intubation. Wright and colleagues reported its use in 289 ED patients, 20 of whom were undergoing intubation. [122] The overall complication rate was 1.4%, including 2 cases of hypotension and 2 cases of respiratory depression. In every case, patients had received other drugs in combination with midazolam that may have been responsible for the observed adverse effects. Most patients in their study (71%) also received fentanyl. The midazolam-fentanyl combination has been reported to provide an excellent level of conscious sedation that has rapid onset and is of short duration.

# PREVENTING THE COMPLICATIONS OF INTUBATION

## The Pressor Response

The pressor response to stimulation of the pharynx, larynx, and trachea was first described by King and coworkers in 1951. [125] This reflex, mediated by the sympathetic nervous system, consists of a transient increase in blood pressure and pulse rate. The

stretching of the hypopharynx that occurs with laryngoscopy is the most common precipitant of the pressor response, but any manipulation of the upper airway, including nasotracheal intubation or suction, may elicit a potent response. An increase in plasma catecholamines, including adrenaline and noradrenaline, is found in association with the pressor response.

Considerable variation exists in the magnitude and duration of the pressor response. Studies of young healthy normotensive subjects have shown that an average increase of 20 to 25 mm Hg in mean arterial pressure occurs with laryngoscopy and intubation. The magnitude of the response increases as the duration of the stimulus increases, reaching a peak at 45 seconds. Data from controls in several studies of patients with a broad spectrum of medical problems reveal blood pressure increases ranging from 14 to 48 mm Hg, with an average of about 30 mm Hg. Similarly, the increase in heart rate ranges from 8 to 45 beats/min, with an average of approximately 30 beats/min. Typically these elevations last less than 5 minutes. The magnitude of the pressor response may be increased in hypertensive patients and those with cardiovascular disease, even if the underlying hypertension is adequately controlled before intubation.

In addition to sinus tachycardia, a number of dysrhythmias have been reported following intubation. These are primarily ventricular in origin and include ectopic beats, bigeminy, and, occasionally, short runs of ventricular tachycardia. Bradyarrhythmias have been reported uncommonly. Electrocardiographic changes suggestive of ischemia have been reported, particularly in patients with dramatic increases in blood pressure. [136] [137] In 1977, Fox and colleagues reported two patients, [138] both of whom deteriorated after induction of anesthesia and orotracheal intubation. This report has been widely quoted as evidence that the pressor response should be prevented. However, no studies have reported comparative data and none have established a direct relationship between the response and subsequent clinical deterioration in a large patient population. It is also unclear that attenuation of the pressor response will prevent dysrhythmias or electrocardiographic evidence of ischemia, although it is prudent to avoid sudden increases in blood pressure in unstable patients with acute cardiac or atherosclerotic vascular disease.

Multiple studies have evaluated procedures to pharmacologically block the pressor response. Lidocaine has been the most extensively evaluated, but the results of these studies are inconclusive.  Although it appears that lidocaine given at 1.5 to 2.0 mg/kg may blunt the response, it is not clear that the reductions reported (10 to 15 mm Hg and 20 beats/min) are of any clinical significance. Other drugs, including thiopentone, sodium nitroprusside, labetalol, nitroglycerin, verapamil, nifedipine, clonidine, fentanyl, sufentanil, etomidate, and magnesium have shown variable responses.  Of these drugs fentanyl may be the most effective. It completely suppresses the pressor response at anesthetic doses of 50 mug/kg,  but considerably smaller doses may also be effective. Two studies  have shown marked suppression of the response at doses of 5 to 6 mug/kg, although in both studies patients also received 5 mg/kg of thiopental. Fentanyl has also been shown to blunt the pressor response when administered in conjunction with etomidate.

It is important to note that even those studies demonstrating blunting of the pressor

response failed to demonstrate that this provided any real benefit to the patients. It is likely that the pressor response is innocuous in the vast majority of patients, but it may be exaggerated and potentially harmful in the presence of preexisting hypertension and cardiovascular disease. [138] In addition, the pressor response may contribute to the rise in ICP that follows laryngoscopy, and therefore it is potentially harmful in patients with intracranial pathology. Administration of lidocaine or fentanyl to blunt the pressor response is appropriate in these subsets of patients.

**Intracranial Hypertension**

Physical stimulation of the respiratory tract by maneuvers such as laryngoscopy, tracheal intubation, and endotracheal suctioning is commonly associated with a brief rise in ICP. The exact mechanism responsible for this rise in ICP is

unknown. One potential mechanism is the coughing and gagging that frequently follows manipulation of the upper airway and subsequent transmission of intrathoracic pressure to the cerebral circulation. An alternative explanation is the catecholamine release that accompanies laryngoscopy, causing a rise in mean arterial pressure and cerebral perfusion pressure. A small rise in ICP has also been reported following administration of succinylcholine.

Although the exact significance of a transient rise in ICP is unknown, it is logical to assume that it may be detrimental in patients with head trauma or intracranial hypertension. A number of drugs, including lidocaine, succinylcholine, and the majority of the anesthesia induction agents, have been studied to determine whether their use prevents this response. Many of the existing clinical data are not particularly relevant to the emergency department setting because they are derived from patients in various stages of general anesthesia, often incorporating a wide variety of drug combinations and doses.

Lidocaine may be an effective agent either because it prevents coughing associated with airway manipulation or because it blunts the pressor response and the resultant rise in cerebral perfusion pressure. At a dose of 1.5 mg/kg IV, lidocaine suppresses coughing induced by citric acid inhalation [156] and at 2.0 mg/kg IV, it suppresses coughing associated with intubation. [157] However, studies have demonstrated conflicting results regarding lidocaine's ability to suppress the rise in ICP that follows airway manipulation. Optimal results have been demonstrated in paralyzed patients, suggesting that paralysis may be the best method to suppress coughing and resultant ICP elevations during intubation. [160] Thus, the use of lidocaine to prevent coughing may have a role only when paralysis is not an option. In the paralyzed patient, lidocaine's effectiveness is uncertain, but it may be beneficial in blunting the pressor response and, secondarily, ICP elevations.

There is good evidence that deep general anesthesia prevents the rise in ICP associated with intubation, although depending on the drug used, anesthesia may compromise cardiovascular performance and critically reduce cerebral blood flow. Consequently, the ideal anesthetic agents to facilitate intubation of patients with acute intracranial pathology may be those that have minimal effects on cardiovascular

performance such as etomidate or fentanyl. Etomidate has been demonstrated to prevent changes in both cerebral perfusion pressure and ICP following tracheal intubation of patients with space-occupying intracranial lesions. [20]

At the present time, the clinical consequences of intubation-induced physiologic changes are not thoroughly understood, nor is the role of drugs in preventing these changes clear. Despite this lack of data, it may be prudent to attempt to protect patients at theoretic risk. The approach outlined in Table 3-4 is recommended.

## CONCLUSION

This chapter has described a number of pharmacologic adjuncts that permit a much more sophisticated approach to intubation of the critically ill patient. As the expertise of physicians practicing in the acute care setting increases, it is appropriate that they incorporate these adjuncts into their airway management protocols. The agents discussed in this

# Chapter 4 - Cricothyrotomy and Translaryngeal Jet Ventilation

**Sharon E. Mace**

Although intubation is the usual method of definitive airway control, clinical situations occur in which intubation is difficult, impossible, or contraindicated. Under these circumstances, cricothyrotomy may be the quickest, easiest, safest, and most effective way to obtain an airway.

Cricothyrotomy is the procedure by which an opening is made in the cricothyroid membrane (Fig. 4-1) to establish an airway. Cricothyrotomy is also known as a laryngostomy, laryngotomy, cricothyrostomy, or coniotomy. *Surgical* cricothyrotomy is the use of a blade to create the opening in the cricothyroid membrane. Once access to the airway is created, oxygen is administered through the opening in the cricothyroid membrane. A needle or small cannula also can be passed percutaneously (i.e., *needle* cricothyrotomy) through the cricothyroid membrane to permit *translaryngeal jet ventilation*. Cricothyrotomy procedures differ from *tracheostomy,* in which entry into the airway is at a lower point (i.e., between the tracheal rings).

An emergency cricothyrotomy allows oxygenation and prevents hypoxemia and its complications, including anoxic encephalopathy and death. Management of the airway is of paramount importance, because the physician has only 3 to 5 minutes in which to obtain an airway and achieve effective ventilation to prevent the complications of hypoxemia. [2]

## BACKGROUND

The importance of securing an airway has been recognized since ancient times. Egyptian tablets dating from 3600 B.C. depict a surgical tracheostomy. [3] Historical records give credit for the first tracheostomy to Asclepiades of Prusa in 124 B.C.[4] In the 2nd century A.D., Galen suggested tracheostomy as the treatment for emergency management of airway obstruction [5] and Antyllus performed a tracheostomy with an incision between the third and fourth tracheal rings. [6]

In the United States, tracheostomies were a known procedure even in colonial times. In 1796, tracheostomies were advocated as a possible treatment for drowning victims. [7] Perhaps the first recorded "successful" case of a surgical cricothyrotomy was in 1852. The cricothyrotomy was successful, but the patient died later from airway stenosis, a complication of the procedure. [8] In 1886, the tracheostomy mortality rate was about 50%, with a high complication rate from airway stenosis, which was usually fatal.

Although tracheostomies and cricothyrotomies were successful and life saving, they were generally done only on severely hypoxic, terminally ill patients, thus contributing to the high morbidity and mortality of the surgical procedure. The fear of complications with the surgical procedure led to a reluctance of the physician to actively intervene until the

patient was near death. "Certainly the delay due to this great dread of tracheostomy was itself largely accountable for the fatality attending its performance."

In 1909, Jackson described the surgical technique for tracheostomy and the factors that are critical for successful tracheostomy or cricothyrotomy. [11] These factors, which are still important today, include (1) obtaining the best airway control possible before surgery; (2) using local anesthesia initially rather than sedation or general anesthesia, which can lead to respiratory arrest in patients with an already compromised airway (although sedation and general anesthesia may be acceptable if the patient is already intubated); (3) emphasizing careful, precise surgical technique with good exposure; (4) using an inert, appropriately sized and shaped tracheostomy tube; and (5) ensuring meticulous postoperative care, which helps avoid contamination or infection and other complications. He noted a surgical mortality of approximately 3%, which is similar to that reported in current series.

Jackson achieved worldwide recognition and patient referrals regarding cricothyrotomy complications. In 1921, Jackson published an investigation of 200 patients referred to him with tracheal stenosis. [12] The study was biased in that patients who did well and had no surgical complications (e.g., no laryngeal stenosis) were not referred to Jackson. Many of the patients had stenosis because of their underlying medical condition and not because of the procedure. Factors relating to surgical technique and postoperative care were not controlled, including aseptic technique, location of the opening in the larynx, and size and type of the tracheostomy tube. Jackson condemned cricothyrotomy because of the complication of subglottic stenosis.

Years later, Brantigan and Grow reported the results of cricothyrotomy on 655 patients. [13] Only 8 patients (0.01%) developed airway stenosis, and none of the patients developed chronic subglottic stenosis. Major vessel hemorrhage and operative misadventures were absent, and the complication rate, which included minor problems, was only 6.1%. The literature supports their conclusions that cricothyrotomy is a safe and effective procedure for airway management with relatively few complications. [When examined at bronchoscopy, no signs of laryngeal stenosis or damage have been noted in patients with cricothyrotomy. [17] Animal studies have documented a normal larynx after cricothyrotomy. [18]

## ANATOMY

Knowledge of the anatomy of the neck and the upper airway is essential when performing a cricothyrotomy. The anatomic landmarks include the hyoid bone, the thyroid cartilage, the cricoid cartilage, and the tracheal rings (see Fig. 4-1) .

The hyoid bone is located midway between the mental protuberance of the mandible and the third cervical vertebra. The midpoint of the body of the hyoid is also the transverse midpoint of the neck and can function as an anchor for stabilizing the airway in an edematous neck. The thyroid cartilage and the cricoid cartilage, both part of the larynx, and the tracheal rings are the major supporting structures of the airway. The trachea is the downward continuation of the larynx. The trachea is supported by cartilaginous rings that are deficient posteriorly. Posteriorly, the trachea lies against the

esophagus.

The thyroid cartilage consists of two approximately quadrilateral-shaped laminae of hyaline cartilage that fuse anteriorly to form the laryngeal prominence. Above the laryngeal

prominence is the superior thyroid notch, where the two laminae are separated. The anterior superior edge of the thyroid cartilage, the laryngeal prominence, is known as the Adam's apple and is usually easily seen in men. Except in the infant, the markedly obese patient, or the patient with massive neck edema, the laryngeal prominence of the thyroid cartilage is usually easily recognized and is palpable. It is probably the most important landmark in the neck when performing a cricothyrotomy.

The cricoid cartilage is the only circumferential ring in the larynx. It is shaped like a signet ring with the shield located posteriorly. The cricoid cartilage forms the inferior border of the cricothyroid membrane. The thyroid cartilage forms the superior border of the cricothyroid membrane.

The highly vascular thyroid gland lies over the trachea at the level of the second and third tracheal rings. If the tracheal rings or the thyroid gland is encountered when performing a cricothyrotomy, then the clinician is too low in the neck and must redirect the incision superiorly toward the cricoid and thyroid cartilages. Avoid the thyroid gland, because marked bleeding may occur if it is injured.

The cricothyroid membrane is a dense fibroelastic membrane located between the thyroid cartilage superiorly and the cricoid cartilage inferiorly; it is bounded laterally by the cricothyroideus muscles. The cricothyroid membrane covers an area that is trapezoidal in shape. The average size of the cricothyroid membrane in the adult is approximately 22 to 30 mm wide and 9 to 10 mm high. The cricothyroid membrane can be identified by palpating a notch, a slight indentation or dip in the skin, inferior to the laryngeal prominence. The cricothyroid membrane is located approximately 2 to 3 cm below the laryngeal prominence in an adult.

Several anatomic and physiologic features make the cricothyroid membrane an excellent choice for gaining access to the airway. The membrane is immediately subcutaneous in location. It does not calcify with age. It has no overlying muscles or fascial layers and no major arteries, veins, or nerves are in the region. Although the right and left cricothyroid arteries, branches of the right and left superior thyroid arteries, respectively, transverse the superior part of the cricothyroid membrane (i.e., nearer the thyroid than the cricoid cartilage) and anastomose in the midline, these vessels generally have not been found to be of clinical significance when performing a cricothyrotomy.

**Anatomic Variations**

The larynx has a few anatomic features that vary according to age and sex. In children, the larynx is much higher than it is in the adult. The larynx descends from approximately

the level of the second cervical vertebra at birth to the level of the fifth or sixth cervical vertebra in the adult.

The laryngeal prominence, the angle at which these two laminae of the thyroid cartilage meet anteriorly, varies from 90 to 120°. This angle is smaller in the male, which makes the laryngeal prominence meet at a more acute angle, or a sharper, more prominent point, than in the female.

In infants, the prominent structures in the anterior neck are the hyoid bone and the cricoid cartilage. The laryngeal prominence does not develop until adolescence and young adulthood.

A few vascular anomalies in the neck may result in a major artery crossing the midline of the neck. This is usually not a problem, because these vascular anomalies are almost always located lower in the neck.

# SURGICAL CRICOTHYROTOMY

### Indications

There are several indications for cricothyrotomy (Table 4-1) . The most common indication is inability to perform endotracheal intubation because intubation is either contraindicated or cannot be done easily and quickly. This decision is always best made by the clinician at the bedside using clinical judgment to weigh the individual circumstances.

Clinical conditions in which endotracheal intubation is difficult at best and is often impossible may include significant bleeding of any of the structures in the upper airway (e.g., massive oral, nasal, or pharyngeal hemorrhage), massive emesis or regurgitation, masseter spasm, clenched teeth, spasm of the larynx or pharynx (or both), laryngeal stenosis, and structural deformities of the upper airway (e.g., congenital or acquired abnormalities or deformities of the oropharynx). Whenever several unsuccessful attempts at endotracheal intubation cause an inordinate delay in airway control and oxygenation, cricothyrotomy is indicated to prevent cerebral anoxic damage. [19]

Obstruction of the upper airway is another indication for cricothyrotomy. [20] It has been stated that patients who are completely obstructed or in extremis are best managed by

**TABLE 4-1** -- Indications for Surgical Cricothyrotomy

Failure of oral or nasal endotracheal intubation
   Massive oral, nasal, or pharyngeal hemorrhage
   Massive regurgitation or emesis
   Masseter spasm
   Clenched teeth
   Structural deformities of oropharynx, congenital or acquired Stenosis of upper airway (pharynx or larynx)
   Laryngospasm
   Mass effect (cancer, tumor, polyp, web, or other mass)
Airway obstruction (partial or complete)
   Nontraumatic
      Oropharyngeal edema
      Laryngospasm
      Mass effect (cancer, tumor, polyp, web, or other mass)
   Traumatic
      Oropharyngeal edema

      Laryngospasm
      Obstruction secondary to a mass effect or displacement
   Stenosis
Traumatic injuries making oral or nasal endotracheal intubation
   difficult or potentially hazardous (relative)
   Maxillofacial injuries
   Cervical spine instability
Need for prolonged intubation
Need for definitive airway during procedures on face, neck, or upper airway
   Laryngeal surgery
   Oral surgery
   Maxillofacial surgery
   Laser surgery
   Bronchoscopy

establishing an airway via the cricothyroid membrane. [21] When simple airway procedures are unsuccessful, cricothyrotomy should be undertaken without delay.

When maxillofacial, cervical spine, head, or soft tissue neck injuries are present, several factors may prevent intubation. These factors include (1) gross distortion of structures, (2) airway obstruction, (3) disruption of upper airway structures, (4) massive emesis, (5) significant hemorrhage, (6) patient discomfort, and (7) the possibility of aggravating existing or suspected injuries that would result in additional damage. In such patients, cricothyrotomy is an excellent alternative for obtaining definitive control of the airway. [22]

Cricothyrotomy should be considered (1) for patients with a known cervical spine injury or a high probability of cervical spine injury in whom definitive airway control is needed

before the cervical spine can be assessed and (2) for patients with certain head injuries, especially basilar skull fractures or cribriform plate fractures. In trauma patients with known or anticipated cervical spine injury, movement of the neck while positioning the patient for intubation is to be minimized because of the possibility of causing additional cervical spine injury. [23] This recommendation has more recently been questioned. [24] *In-line stabilization of the neck with minimal movement during direct laryngoscopy appears to be a relatively safe alternative during emergent intubation of the trauma patient.* [25] [26]

Cricothyrotomy has several advantages over tracheostomy when prolonged intubation is needed (Table 4-2) . [27] [28] Cricothyrotomy has been used for definitive airway control before elective surgery of the face, head, and neck. [29] Translaryngeal jet ventilation has become a routine method of ventilation during procedures (both endoscopy and surgery) on the upper airway. [30] This ventilation technique allows better access to and visualization of the upper airway for the surgeon or endoscopist than is possible with intubation from above the larynx, which often obscures and limits the surgical field. It also decreases the chance of flames or a "mini-explosion,"

---

**TABLE 4-2** -- Advantages of Surgical Cricothyrotomy Over Tracheostomy

Advantages due to anatomic considerations
   Immediate subcutaneous location (vs deep dissection)
   Absence of critical structures overlying cricothyroid membrane
   Easily seen landmarks, recognizable from the surface anatomy
   Less chance of esophageal injury (circumferential cricoid cartilage vs deficient tracheal cartilage posteriorly)
   Further away from mediastinum, dome of pleura (less encroachment on thoracic structures)
Overall advantages
   Easier to do, faster, safer
   Does not need to be done in an operating room
   Less need for hyperextension of the neck
   Better cosmetic appearance of scar (shorter, less adherent)
   Decreased incidence of late complications (e.g., swallowing problems, voice disturbances, fistulas, erosion of innominate artery)
   Decreased incidence of early complications (e.g., pneumothorax, pneumomediastinum, mediastinal perforation, esophageal injury) because of less encroachment on the mediastinum and other critical structures
   Can be done quickly by non-surgeons
   Requires a minimum of instruments

| TABLE 4-3 -- Contraindications to Surgical Cricothyrotomy |

| Absolute contraindications<br>   Endotracheal intubation can be accomplished easily and quickly, and no contraindications to endotracheal intubation are present<br>   Transection of trachea with retraction of distal end into the mediastinum<br>   Fractured larynx or significant damage to the cricoid cartilage or larynx<br>Relative contraindications *<br>   For infants and toddlers (<5 yr) transtracheal ventilation may be preferred over surgical cricothyrotomy<br>   Bleeding diathesis<br>   Patients with massive neck edema (may use modified technique for these patients)<br>   Acute laryngeal disease |

Relative contraindications may be overlooked in the true emergency situation because it is more important to obtain an airway and to avoid hypoxemia.

which may occur during laser surgery or during other procedures that require flammable anesthetics or other gases. [31]

## Cricothyrotomy vs Tracheostomy

The decreased incidence of complications with cricothyrotomy compared with that of tracheostomy is due at least partly to anatomy. [32] Anatomic considerations make tracheostomy a relatively complicated and difficult procedure. Many delicate complex structures in the neck lie in close proximity to the trachea. Less encroachment on the mediastinum occurs with a cricothyrotomy than with a tracheostomy, because the cricothyroid membrane is further away from the mediastinum and other critical structures. Early complications, including pneumothorax, pneumomediastinum, and mediastinal perforation, occur less often with cricothyrotomy. Because the tracheal cartilage, unlike the cricoid and thyroid cartilage, is deficient posteriorly, the chance of damage to the posterior structures (e.g., esophagus) lying immediately behind the airway is greater with a tracheostomy. The incidence of late complications, including fistulas, erosion of the innominate vessels, swallowing problems, and voice disturbances, is less with cricothyrotomy.

Cricothyrotomy is preferred over tracheostomy for definitive emergency management of the airway when intubation is impossible or contraindicated. The few exceptions are in children 5 years old (although some recommend needle cricothyrotomy with translaryngeal jet ventilation rather than tracheostomy) and for transection of the trachea with retraction of the distal trachea into the mediastinum.

## Contraindications

Cricothyrotomy has relatively few contraindications (Table 4-3) . Cricothyrotomy should not be done in patients who can be quickly, easily, and safely intubated. Transection of the trachea with retraction of the distal end is a contraindication to cricothyrotomy. A fractured larynx or other significant damage to the larynx or cricoid cartilage is another contraindication. [33]

| **TABLE 4-4** -- Equipment for Surgical Cricothyrotomy Tray |
| --- |
| Scalpel with No. 15 blade and scalpel with No. 11 blade<br>Tracheal dilator (Trousseau dilator) or spreader<br>Two hemostats<br>Scissors<br>Tracheal hook<br>Needle holder<br>Tracheostomy tube (appropriate-size Portex or Shiley tube--No. 5-6 in an adult)<br>25-ga needle and syringe containing lidocaine with epinephrine (for local anesthesia)<br>Preparation solution<br>Sterile gauze pads<br>Sterile tracheal suction catheter<br>Suture or circumferential tie (to secure tracheostomy tube in place) |

Factors shown to be associated with subglottic stenosis include prolonged intubation, underlying laryngeal disease, and younger age (e.g., infants and small children). [34] Some believe that these conditions are relative contraindications to cricothyrotomy and that a cricothyrotomy should be converted immediately to a surgical tracheostomy. [35] Current studies indicate that subglottic stenosis is not a common complication of cricothyrotomy, even in the presence of laryngeal pathology, and that patients can have a cricothyrotomy for months without having subglottic stenosis. These considerations (i.e., prolonged intubation and underlying laryngeal disease) are no longer absolute contraindications to cricothyrotomy.

A bleeding diathesis is not an absolute contraindication to emergency cricothyrotomy, because it is easier to obtain hemostasis with a cricothyrotomy than with a tracheostomy. Loss of cervical landmarks with massive neck edema makes the procedure more difficult, although one approach using a measured estimation of the cricothyroid membrane location in this setting is promising. [36] These relative

contraindications may be overlooked in a true emergency, i.e., when obtaining an airway is imperative.

## Equipment

In the out-of-hospital setting, the only essential items are a sharp blade and a hollow tube to maintain the airway. In the emergency department, the optimal instruments needed for surgical cricothyrotomy should be easily accessible. A sterile tray containing all the necessary instruments in an organized fashion should be part of the standard equipment stocked in the major resuscitation area (Table 4-4) . Prepackaged percutaneous kits are also available.

An appropriate-sized tracheostomy tube should be selected (Table 4-5) . A small tube becomes obstructed more easily by secretions, whereas a large tube may damage the surrounding cartilage and lead to a fractured larynx. In an adult, a tracheostomy tube with an 8-mm internal diameter (ID), such as a No. 5 Portex or Shiley tube, is usually an appropriate size (see Table 4-5) .

If an appropriately sized tracheostomy tube is not available immediately, an endotracheal tube can be used as is or modified for use as a tracheostomy tube (Fig 4-2) . The uncuffed (proximal) end of the endotracheal tube is cut to an appropriate length (see Fig. 4-2 ) *A*). The adapter is then attached to the cut end (see Fig. 4-2 *B*), and the modified endotracheal tube is inserted like any tracheostomy tube. After insertion, the cuff of the endotracheal tube should be inflated, if possible.

The essential supplemental equipment for airway management, specifically supplemental oxygen, suction, and a bag-valve device, should be readily available.

## Procedure

### Preparation and Positioning

In a truly emergent situation, rapid airway access is critical, and there may not be enough time even for local anesthesia. Because of the dangers of respiratory depression in a patient who may have a compromised airway already, sedation and general anesthesia may be contraindicated.

The patient is positioned to expose the neck and its landmarks. If there are no contraindications, such as known

---

**TABLE 4-5** -- Tracheostomy Tube Sizes

| Age | Internal Diameter of Tracheostomy Tube (mm) | Holinger or Magill Tube Size | Internal Diameter of Endotracheal Tube (mm) |
|---|---|---|---|
| Premature (<1.8 kg; <4 lb) | | 000 | 2.5 |
| Premature (1.8 kg; 4 lb) | | 00 | 2.5 |
| Newborn | 2.5 | 00 or 0 | 3.0 |
| 0-6 mo | 3.5 | 0 | 3.5 |

|---|---|---|---|
| 10 yr | 7.0 | 4 | 7.0 |
| 12 yr | 7.5 | 5 | 7.5 |
| 14 yr | 8.0 | 5 | 7.5 |
| Adult female | 8.0-8.5 | 5 | 7.5-8.5 |
| Adult male | 8.5-9.5 | 6 | 8.0-9.0 |

**Figure 4-2** Modification of an endotracheal tube for use as a tracheostomy tube. *A,* An appropriate-sized endotracheal tube is cut to an appropriate length. *B,* An adapter is attached to the cut end before the modified endotracheal tube is inserted into the larynx via the opening in the cricothyroid membrane.

or suspected cervical spine injury, the patient's head should be hyperextended.

The cricothyroid membrane is located by identifying the dip or notch in the neck below the laryngeal prominence. The cricothyroid membrane is bounded by the thyroid cartilage superiorly and the cricoid cartilage inferiorly. The landmarks are most easily found by placing the index finger on the prominence of the thyroid cartilage and slowly palpating downward until the finger "drops off" the thyroid cartilage and onto the cricoid membrane (Fig. 4-3 *A*). When the tip of the finger is in the proper position, the hard cricoid cartilage may be palpated with the fat pad of the index finger. If time permits, local anesthesia and skin preparation with povidone-iodine may be used. The skin and subcutaneous tissue immediately above the cricothyroid membrane may be infiltrated using lidocaine with epinephrine.

**Incision and Tube Placement**

A skin incision is made over the cricoid membrane. A midline longitudinal (vertical) skin incision about 3 to 4 cm long is made for an emergency cricothyrotomy. For an elective cricothyrotomy, a more cosmetic 2-cm transverse (horizontal) skin incision can be made. A longitudinal skin incision is preferred during an emergency, because if the skin incision is too high or too low, a longitudinal skin incision merely needs to be extended, thus saving time and avoiding a second incision. As an option, one can insert a 20- to 25-ga needle through the cricothyroid membrane and confirm intra-airway positioning by aspirating air. The needle can be left in place to serve as a guide for the surgical

procedure and then removed before insertion of the tracheostomy tube.

The larynx is stabilized by holding it between the nondominant thumb and middle finger or by using a tracheal hook. After the skin incision, a short horizontal (transverse) stabbing incision about 1 cm long is made in the lower part of the cricothyroid membrane (i.e., nearer the cricoid cartilage than the thyroid cartilage to avoid the cricothyroid arteries). The stabbing incision is made in such a way that only the tip of the scalpel blade enters the trachea (see Fig. 4-3) .

Curved Mayo scissors are inserted beside the scalpel blade and then spread horizontally to widen the space. An alternative method is to widen the opening by using a scalpel handle and turning the scalpel 90° ("longitudinally" with respect to the patient) instead of using curved Mayo scissors. The scalpel handle then is removed and a tracheal (Trousseau) dilator or curved hemostat is inserted into the incision site in the cricothyroid membrane. The dilator is then opened to enlarge the opening in the cricothyroid membrane.

When attempting to insert the tracheostomy tube, the larynx may be displaced posteriorly. Posterior displacement of the larynx may make it difficult or impossible to insert the tracheostomy tube. Stabilization of the larynx is important to lift and hold the larynx anteriorly in proper anatomic position so that this potential problem can be avoided. The tracheostomy tube is inserted between the tracheal dilator or curved hemostat blades (see Fig. 4-3 *E*). The dilator or hemostat is then removed. The cuff of the tracheostomy tube is inflated.

In an adult, a No. 5 or 6 Shiley tracheostomy tube is usually an appropriate size (No. 5 for an adult female and No. 6 for an adult male). If edema is present, a smaller (No. 4) Shiley tube may be used. Other tube size guidelines are provided in Table 4-5 .

If a tracheostomy tube is not available immediately, then an endotracheal tube can be used as a temporary airway device. The endotracheal tube can be replaced later when an appropriate-sized tracheostomy tube is available.

The lungs are ventilated, and proper tube placement should be ensured. The tracheostomy tube is secured in place via a circumferential tie around the neck or by suturing. After confirming proper tube placement, the tracheostomy tube may be attached to a ventilator or a bag-valve device. Flexible connector tubing is recommended to avoid excessive forces on the tracheal wall during mechanical ventilation.

**Precautions**

The skin incision and the incision in the cricothyroid membrane should not be made too far laterally (see Figs. 4-1 and 4-3 *A*). A central incision will decrease the chance of hemorrhage due to laceration of vessels. The skin incision should not be made too far caudally in the neck, thus avoiding hemorrhage from and damage to the thyroid gland.

The stabbing incision should be made in the lower half of the cricothyroid membrane (i.e., nearer the cricoid cartilage than the thyroid cartilage) in an attempt to avoid bleeding from the cricothyroid arteries, which course superiorly across the cricothyroid membrane near the lower edge of the thyroid cartilage.

Transection of the cricoid cartilage or tracheal rings should be avoided. These structures help maintain the stability of the laryngeal lumen. Injury to these structures may predispose to late complications, including subglottic stenosis.

The scalpel should be directed in a caudal direction, so that injury to the vocal cords is avoided. The vocal cords are located above the cricothyroid membrane and are protected by the thyroid cartilage on three sides. When a cricothyrotomy is being done, the needle or scalpel should be directed posteriorly at a 90° angle to the cricothyroid membrane (see Fig. 4-3) .

The physician should avoid making a blind stab with the scalpel in the region. Controlled, anatomically placed incisions will minimize hemorrhage and injury to any of the adjacent structures.

The handle of the scalpel should be held in such a way that only the tip of the scalpel blade can enter the trachea during the stab incision through the cricothyroid membrane. For control, the physician should place the thumb and index finger low on the handle of the scalpel (just above the scalpel blade). A controlled stab incision should help avoid injury to the posterior wall of the trachea, esophagus, and other posterior structures by limiting the depth of scalpel insertion.

Placement of too large a tracheostomy tube through the cricothyroid membrane should be avoided. Placement of an oversized tracheostomy tube can lead to a fractured larynx. [25] In the adult, the average size of the cricothyroid membrane is about 2 to 3 cm wide and 1 cm high. Thus, the appropriate tracheostomy tube in an adult is one with an 8- to 9-mm internal diameter (a No. 5 in an adult female and a No. 6 in an adult male) unless edema is present, in which case a smaller size (No. 4) is used.

**The Patient with Massive Neck Swelling**

One method of surgical cricothyrotomy uses the hyoid bone as a landmark and an anchor to stabilize the mobile airway in a patient with massive neck edema. [37] [38] The horizontal midpoint of the body of the hyoid is also the midpoint of the neck. The key measurement in this technique is distance from the angle of the mandible to the mental protuberance of the chin (line *A* on Fig. 4-4) . Distances can be measured using a piece of suture or a string. This distance from the angle of the mandible to the mentum is divided in half.

A point is identified on the anterior midline of the neck below the chin (point *C*), which equals line *B* or one half the length of the line *A* (see Fig. 4-4) . A needle is placed  at a point *C* and directed toward the midline so that it will reach an imaginary line connecting

both angles of the mandible. The tip of the needle should hit the hyoid bone. A large-bore (e.g., 18-ga spinal needle) should be used, as the needle must be long enough to pass through massive neck swelling and hit the hyoid bone. If the hyoid bone is not found, the angle of the needle should be adjusted.

When the hyoid bone is found, the needle is left in position, and a No. 11 blade is inserted along the needle tract until the hyoid bone is reached. A skin hook is placed alongside the scalpel's tract and under the hyoid bone to retract the hyoid superiorly and anteriorly. A longitudinal skin incision is made inferiorly from the skin hook with care taken to stay in the midline. The hyoid bone acts as a fulcrum, holding and stabilizing the larynx in position, so that the incision will stay in the midline despite massive swelling of the neck. The incision is extended caudad over the thyroid cartilage until the cricothyroid membrane is exposed. The remainder of the procedure follows the routine steps for cricothyrotomy. The only additional supplies needed for this modification of cricothyrotomy in patients with massive neck edema are the suture (or string) to measure the distance from the angle of the mandible to the mentum of the chin and an 18-ga spinal needle to find the hyoid bone.

### Infant and Children

Cricothyrotomy, as with tracheostomy, is technically more difficult in infants and children than in adults and may have a higher rate of problems or complications. Because the laryngeal prominence is not well developed until adolescence and young adulthood, the most prominent structures in the anterior neck of the infant or child are the hyoid bone and the cricoid cartilage. In children <5 years old, the cricoid is the narrowest part of the airway, and the cricothyroid membrane is quite small. Furthermore, the larynx is higher, relatively less accessible, and smaller in the child than in the adult.

Some advocate tracheostomy rather than cricothyrotomy in infants and children (when endotracheal intubation is contraindicated or impossible), because of the difficulty in palpating and identifying the important landmarks of the neck, and because of the small diameter of the cricoid cartilage. Others note that emergency surgical cricothyrotomy has fewer complications than emergency tracheostomy in infants and children. It has been suggested that a cricothyrotomy be converted to a tracheostomy when the infant or child is stabilized, to reduce the possibility of subglottic stenosis.

### Complications

The incidence of complications for an elective surgical cricothyrotomy is approximately 6 to 8%. The complication rate for an emergency cricothyrotomy ranges from 9 to 31%. [39] [40] The complication rate for emergency cricothyrotomy compares favorably with that for tracheostomy, which has an average complication rate of approximately 45%. [41] The mortality rate for cricothyrotomy of 0.15% is less than that for tracheostomy, which is 1.6 to 5.0% and as high as 16% in recent series. [42] [43] [44] In general, there has been a higher incidence of complications with cricothyrotomy in infants and children than in adults. This is also true for tracheostomy. Tumor, inflammation, other masses, certain congenital anomalies, and significant trauma may distort the anatomic features of the neck and airway, creating additional difficulty in performing a cricothyrotomy and

increasing the complication rate for this procedure.

Minor complications are more common than serious complications (Table 4-6) . Early complications are more frequent than late complications. In one series of patients who had emergency cricothyrotomies, the overall incidence of complications was 23% with no long-term complications. [45]

The most common complications are bleeding, incorrect site of tube placement, unsuccessful tube placement, and prolonged procedure time (see Table 4-6) . The overall procedure time for cricothyrotomy should be less than 3 minutes. It is not unusual for surgical cricothyrotomy to be completed in 30 to 60 seconds.

---

**TABLE 4-6** -- Complications of Surgical Cricothyrotomy

Immediate or early complications
   Common
      Bleeding, hematoma
      Incorrect tube placement
      Unsuccessful tube placement
      Prolonged procedure time
      Subcutaneous emphysema
      Obstruction
   Infrequent
      Esophageal perforation
      Mediastinal perforation
      Pneumothorax, pneumomediastinum
      Vocal cord injury
      Laryngeal fracture or disruption of laryngeal cartilage
      Aspiration
Late complications
   Most common
      Obstructive problems
      Voice changes or dysphonia
      Infections
      Late bleeding
      Persistent stoma
      Subjective feeling of lump in the throat
   Infrequent complications
      Subglottic or glottic stenosis
      Tracheoesophageal fistula
      Tracheomalacia

Bleeding from the procedure is usually minor and occurs early. Such bleeding can usually be controlled by packing the cricothyrotomy site with gauze. It is unusual for bleeding vessels to require ligation. Persistent hemorrhage is usually attributable to vessels located at the edges of a transverse skin incision. This complication is minimized if a longitudinal skin incision is made. [46] Potential bleeding may be minimized by making the stab incision in the lower part of the cricothyroid membrane near the cricoid cartilage to avoid the cricothyroid arteries. Major bleeding generally has not been a problem. [47] [48] One cadaver study noted a high number of small vessels in the region of the cricothyroid membrane that are at risk during a cricothyrotomy. Hence, hemorrhage could still be a problem even if the technique of cricothyrotomy is done correctly and all the guidelines for the procedure are followed. [49] Even a small amount of bleeding could be life-threatening if it occurs endotracheally, with resultant pneumonitis or suffocation. [50] The mortality from acute bleeding during a tracheostomy has been attributed to airway obstruction from the blood and not from volume loss. [51] In the management of postcricothyrotomy or post-tracheostomy bleeding, the airway is protected if the tracheostomy tube is in place and the cuff is inflated. If the airway is protected, then hemorrhage control (i.e., local pressure on the bleeding vessels and, if necessary, ligature) can be done in a controlled fashion.

An incorrectly placed transverse skin incision may lead to bleeding and incorrect or unsuccessful tube placement. Too low a skin incision may lead to tube placement between the tracheal rings. In an emergency, a longitudinal skin incision is preferred, because a misplaced longitudinal skin incision, whether too high or too low, can be easily extended. [52]

Other less common complications include infection and airway obstruction. [53] An indwelling tube will become colonized by bacteria even if meticulous care is taken, and infection can result. Infection can occur in the structures or tissues of the neck and in the tracheobronchial tree. Potential infections include cellulitis, perichondritis, abscess in the incision site, and laryngotracheitis.

Acute airway obstruction can occur with tracheostomy or cricothyrotomy. The most common cause of acute airway obstruction is a mucus plug. A mucus plug that causes obstruction should be cleared from the airway by careful suctioning, using sterile technique (see Chapter 5) . If this cannot be accomplished, then the entire tracheostomy tube may need to be changed. Less frequently, acute airway obstruction can be caused by overinflation of the tracheostomy balloon with herniation of the balloon over the tip of the tracheostomy tube or by retrograde intubation of the pharynx. [54] The tracheostomy tube can be passed into a subcutaneous fascial or tissue plane instead of into the trachea. This complication can occur during insertion of the tracheostomy tube or, more commonly, during a tube change, especially during the immediate postoperative period.

Long-term complications following cricothyrotomy are unusual. [55] The major long-term complication is a change in voice or dysphonia. [56] Laryngeal damage may occur

secondary to a laryngeal fracture caused by using a tracheostomy tube that is too large for the size of the cricothyroid membrane. Dysphonia can also be caused by direct injury to the vocal cords.

Other late and rare complications include a suture sinus, a subjective feeling of a lump in the throat, a persistent stoma, chondritis of the thyroid or cricoid cartilage, and subglottic or glottic stenosis. Swallowing problems have been reported in tracheostomy patients [57] but not in cricothyrotomy patients.

Airway stenosis is a potential complication whenever a tube is placed in the airway. Airway stenosis can occur with intubation, cricothyrotomy, or tracheostomy. The most common cause of subglottic stenosis is endotracheal intubation and not cricothyrotomy or tracheostomy. [58] The pathophysiology of subglottic stenosis involves mucosal ulceration and damage secondary to a tube eroding the mucosal surface and laryngeal disease along with bacterial colonization of the region. Excessive cuff pressures, frequent tube motion, and rigid tubes that are anatomically incorrect, contribute to mucosal damage. The use of flexible, anatomically correct tubes with low-pressure cuffs and flexible tubing between the tube and the ventilator will minimize mucosal damage.

Prolonged endotracheal intubation followed by tracheostomy or cricothyrotomy is associated with a higher incidence of subglottic stenosis than with either endotracheal intubation or the surgical procedure (tracheostomy or cricothyrotomy) alone. [59] The airway stenosis produced by an indwelling tube is generally located at the cuff site of the tube. If airway stenosis occurs with a standard tracheostomy, the stenosis occurs quite distal in the trachea, thus making it difficult to reach during surgical repair. Early aggressive surgical management of granulation associated with mucosal injury has been successful in limiting chronic airway stenosis.  In recent studies of cricothyrotomy, subglottic or glottic stenosis is rarely encountered if at all.

There are other theoretical complications of cricothyrotomy. These include pneumothorax, pneumomediastinum, major vessel hemorrhage, tracheoesophageal fistula, and esophageal perforation. These complications are seen with tracheostomy but have not yet been reported as complications of cricothyrotomy.

The complications of asphyxia, including dysrhythmias and cardiac arrest, during the performance of tracheostomy or cricothyrotomy are generally due to the lack of adequate oxygenation and not to a vagal reaction. Because cricothyrotomy is one of the easiest, quickest, and safest ways to achieve definitive airway control and oxygenation, the complications of hypoxemia should occur less commonly than with tracheostomy when performed in critically ill patients.

## PERCUTANEOUS TRANSLARYNGEAL JET VENTILATION (NEEDLE CRICOTHYROTOMY)

### Overview

Needle cricothyrotomy is a percutaneous technique in which a needle is placed through

the skin, the subcutaneous tissue, and the cricothyroid membrane without using a formal incision. This airway access procedure is *ideally* followed by intermittent high pressure administration of oxygen through the cannula in the cricothyroid membrane ( *translaryngeal jet ventilation*). Only when a sufficiently large catheter (generally 3 mm ID) is inserted, can a low-pressure ventilation source (e.g., bag-valve device) be used to partially support ventilation in the adult. However, a low-pressure ventilation source can be effective for ventilation through a 12- to 14-ga IV catheter in very small infants (5 kg) and may partially support ventilation in larger infants without complete airway obstruction.

The technique of puncture of the cricothyroid membrane is relatively simple and has many uses, ranging from obtaining sputum samples, to giving local anesthesia before intubation, to ventilating the patient.  Whether the lungs can be ventilated adequately via a cannula in the cricothyroid membrane has been debated. We now know that percutaneous translaryngeal ventilation can be an effective and relatively safe procedure for obtaining and maintaining an airway for extended periods of time provided that appropriate equipment and techniques of ventilation are used. [66]

Historically, oxygen was simply passed through the needle or cannula in the cricothyroid membrane ( *apneic oxygenation*). In this way, hypoxia was treated, and tissue oxygenation was generally adequate. Clinical studies and animal experiments noted that although the partial pressure of $O_2$ ($pO_2$ ) was adequate, $CO_2$ was retained, and the elevated partial pressure of $CO_2$ ($pCO_2$ ) led to respiratory acidosis. The oxygenation could be maintained for only about 30 minutes because of the severe hypercapnia and resultant respiratory acidosis, even when the hypoxia was treated successfully. [67] This procedure, whereby oxygen is run continuously through a needle or cannula in the cricothyroid membrane, is referred to as *translaryngeal oxygenation*.

The solution to avoiding a rise in $pCO_2$ and respiratory acidosis is to ventilate the patient, allowing time for both inhalation and exhalation, thus simulating normal respiration. [68] Intermittent bursts of oxygen provide sufficient "tidal volume" and time for exhalation thus avoiding hypercapnia and respiratory acidosis. *Translaryngeal jet ventilation*, is the

ventilation of the lungs by intermittent bursts of oxygen through a needle or cannula in the cricothyroid membrane. The technique can supply adequate ventilation up to high degrees of airway obstruction. Percutaneous *transtracheal jet ventilation* is the same procedure except that the cannula is placed through the larynx into the trachea.

## Physiology

The idea of gas insufflation via an opening in the trachea was described in the early 17th century, [69] although the current usage of the technique has only become popular in the last 25 years. A lack of understanding of the differences between transtracheal oxygenation and ventilation and a failure to standardize the technique itself (with regard to such factors as pressure, volume, intermittent vs continuous administration of air vs oxygen, size of opening in the membrane, and location of opening in the airway) has led

to conflicting reports in the literature and to many misconceptions. [70]

Studies as early as 1909 showed that animals could survive for approximately 30 minutes when oxygen was given via a needle placed in the cricothyroid membrane. [71] Reed and coworkers, in 1954, showed that animals could be kept alive for a longer period of time with a normal pH if they were ventilated with intermittent bursts of compressed air instead of a continuous flow of oxygen. [72] The key to avoiding respiratory acidosis and maintaining a normal pH was the use of a method allowing for adequate ventilation, not just a continuous inflow of oxygen or air (as with apneic oxygenation).

A popular misconception is that percutaneous transtracheal ventilation is a temporizing procedure, good for only 30 minutes at best. Animal experiments and clinical studies have demonstrated that transtracheal ventilation is an effective, quick, fairly simple, and safe way to obtain and maintain an airway for a prolonged period of time. [73] Percutaneous translaryngeal ventilation with an adequate-sized cannula, appropriate ventilation pressures, sufficient tidal volumes, and adequate exhalation times can provide adequate ventilation for extended periods. [74]

Transtracheal jet ventilation has been used extensively as a means of ventilation during surgery and procedures of the upper airway.  Translaryngeal jet ventilation may be used even with partial airway obstruction.] Percutaneous translaryngeal jet ventilation is a rapid procedure for obtaining airway control in both elective and emergency situations in patients of all ages and in many clinical situations.

The advantages of needle cricothyrotomy with translaryngeal jet ventilation over surgical cricothyrotomy include (Table 4-7) faster performance (may take only 10 seconds), easier performance, less equipment and smaller surgical setup required, no need for an assistant, smaller scar, less bleeding, expulsion of oropharyngeal secretions and other particles or small objects from the proximal trachea, less tracheal erosion, and less frequent subglottic or glottic stenosis (see Table 4-1) . Some of the advantages are a result of the smaller size of the opening and the percutaneous technique.

The disadvantages of percutaneous transtracheal jet ventilation are (1) incomplete control of the airway, with a greater potential for aspiration than with a cuffed tracheal

---

**TABLE 4-7** -- Advantages of Percutaneous Translaryngeal Ventilation vs Surgical Cricothyrotomy

Faster (may take as little as 10 sec vs 30 sec to 3 min for surgical cricothyrotomy)
Less bleeding (due to smaller opening, smaller incision)
Simpler technique, easier to perform
Does not need an assistant, can be done by nonsurgeons
Requires fewer instruments
Lesser need for extensive surgical setup (lighting, equipment, and preparation)
Smaller scar (stoma is only as large as the size of the tube)
Less tracheal erosion
Less subglottic or glottic stenosis
Forces oropharyngeal secretions out of the proximal trachea
May force foreign body out of proximal trachea with a partial airway obstruction

tube; (2) likelihood of barotrauma (subcutaneous emphysema or pneumothorax) if exhalation is inadequate and airway pressure is elevated; and (3) inability to perform adequate suctioning through a percutaneous catheter setup. Airway protection during transtracheal ventilation is attained by positioning the patient to allow drainage of secretions away from the larynx during expiration, so upward gas flow through the larynx causes secretions and blood, for example, to be blown away from the larynx. [82]

**Indications**

Indications for needle cricothyrotomy with translaryngeal jet ventilation are similar to those for surgical cricothyrotomy. Cricothyrotomy is indicated in any situation in which intubation is contraindicated or cannot be performed (see Table 4-1) . Failure to achieve endotracheal intubation in a timely fashion, and a subsequent inordinate delay in definitive airway control and oxygenation, is an indication for needle or surgical cricothyrotomy to prevent hypoxemia.

Percutaneous translaryngeal ventilation can be used in a patient with airway obstruction, but it requires an adequate-sized catheter or catheters. [83] [84] Translaryngeal ventilation has been recommended as the procedure of choice for airway control and oxygenation during surgery and procedures on the upper airway. [85] Percutaneous translaryngeal ventilation has been used as an elective procedure and in patients of all ages in an emergency (even premature infants), for extended periods of time. [86]

**Contraindications**

The absolute contraindications to surgical or needle cricothyrotomy are (1) the ability to accomplish endotracheal intubation easily and rapidly; (2) retraction of the distal end of the trachea into the mediastinum after tracheal transection; and (3) occurrence of known significant direct damage to the cricoid cartilage or larynx (see Table 4-3) . [87]

Known complete airway obstruction requires an adequate-sized catheter or catheters to

avoid barotrauma and hypercarbia. Barotrauma with high pressures occurring in the trachea can lead to complications such as a pneumothorax and/or pneumomediastinum during percutaneous transtracheal ventilation. [88] If intratracheal pressures 20 cm $H_2O$ are maintained, the complication rate of percutaneous transtracheal ventilation is low. If complete upper airway obstruction is present, surgical cricothyrotomy is preferred over percutaneous translaryngeal ventilation, although percutaneous translaryngeal ventilation could be used with partial or complete airway obstruction provided appropriate-sized catheters are used. [89]

Relative contraindications to percutaneous translaryngeal ventilation are different from those for surgical cricothyrotomy. Age <5 years has been mentioned as a relative contraindication to surgical cricothyrotomy. Age is not a factor in percutaneous translaryngeal ventilation. Percutaneous translaryngeal ventilation has been recommended by some as the procedure of choice in infants and young children as a means of obtaining an airway, especially in an emergency, rather than tracheostomy or surgical cricothyrotomy. [90]

## Equipment

Translaryngeal jet ventilation requires three components: an oxygen supply at 50 psi, an in-line one-way "valve" to allow for the intermittent administration of oxygen, and a needle or cannula with a bore 13 or 14 ga in the cricothyroid membrane (Table 4-8) .

### Oxygen Supply

The oxygen supply must be at a pressure of 50 psi to deliver enough volume to ventilate the lungs rapidly between periods of exhalation through the glottic opening. An oxygen source of 50 psi can be obtained by attaching a connector to the piped oxygen wall line found in any emergency department, attaching the tubing to the flush valve of an anesthetic machine, or attaching the oxygen tubing directly into an oxygen tank line (regulator) but not to the flow valve of the oxygen cylinder. The oxygen tanks in ambulances or other patient transport vehicles for prehospital care should have two components: (1) an outlet that leads directly into the cylinder line, and (2) a simple, easy-to-connect device that allows the oxygen hose to be quickly attached to the outlet.

Stewart recommends unscrewing the demand valve connection from the oxygen regulator of the tank and rapidly

---

**TABLE 4-8** -- Equipment for Needle Cricothyrotomy and Translaryngeal Jet Ventilation

Oxygen source
   High-pressure oxygen source at 50 psi
   Deliver 100% oxygen at 20 bursts/minute with I:E = 1:4
Manual jet ventilator device
   High-pressure tubing (to be attached to cannula or catheter and oxygen at other end with the manual jet ventilator device in the middle)
   Manual jet ventilator device (Y-connector or push-button device) to allow for ventilation with inhalation and exhalation
Cannula
   Large bore (gauge less than or equal to 13- or 14-ga needle) with a Teflon or plastic cannula or, alternatively, one of the commercial cricothyrotomy devices, or 9 Fr catheter

I , inhalation; E, exhalation.

connecting the oxygen hose that has a nipple in place for fitting into the outlet. [69] He suggests leaving a small wrench fastened to the oxygen hose to allow a rapid transfer.

Two key points should be remembered: (1) high-pressure tubing should be used throughout the system, and (2) all connections and attachments should be well secured to avoid any disconnection under high pressure. Ligatures or other fasteners may be helpful in securing the attachments.

**"Valve" Apparatus**

It is essential to have the proper attachment for delivery of oxygen to the cannula or needle. Whatever the device or valve apparatus selected, it is critical to have all of the equipment ready, all of the connections available, and everything easily accessible. The apparatus can be gathered together and placed in one bag or kit and should be stored with the other airway management equipment.

First, high-pressure tubing goes from the oxygen source at 50 psi to a manually controlled device, which is then connected via high-pressure tubing to the cannula or needle in the cricothyroid membrane (Fig. 4-5) . Stewart [70] recommends the manual valve by Instrumentation Industries (Bethel Park, Pa), although others such as the Manujet by VBM (Germany) are also available. [69] A list of other "valve" apparatus options with varying costs ($5 to $200) has been published elsewhere. [91]

Note that standard commercial demand valves deliver only 60 cm $H_2$ O (approximately 0.9 psi). [87] Systems using makeshift bag-valve assemblies (Fig. 4-6) do slightly better, but may deliver as little as 12 to 15 L/min of oxygen using 14- and 13-ga catheters,

respectively.

## Cannula or Needle

The third piece of equipment required is the cannula. A 13- or 14-ga needle catheter with a length of about 2 cm (or 1 inch) or a 3-mm ID cannula is preferred for percutaneous translaryngeal ventilation. The size of the needle or cannula is critical. [92] Too small a cannula will not allow for sufficient ventilation, causing hypercapnia and even hypoxemia to develop.

Modifications for the cannula have been suggested: side holes, a slight curve, and a plate or flange. The advantage of side holes is that they will help keep the end or point of the cannula away from just one area of the tracheal wall. Thus, the full force of the 50 psi oxygen source is not directed at just one area of the laryngeal wall but is distributed in the larynx. The shape of the cannula may facilitate its initial placement or enhance complications. A fixation plate, flange, or side handle helps secure the cannula into place. A snug fit of the cannula will help prevent subcutaneous emphysema and ventilation of overlying soft tissue.

The use of a large-bore (9 Fr ID with 13 Fr outside diameter [OD] and length of 6 cm) has been recommended instead of a 14-ga IV catheter. The large-bore cricothyrotomy catheter has several advantages: less chance of kinking or plugging up, improved mechanical structure, and the ability to be used with jet ventilation or bag-valve device ventilation.

## Commercial Kits

Cannulas designed for cricothyrotomy or percutaneous translaryngeal ventilation are commercially available (Table 4-9) . Several studies suggest that the "commercial" kits may have a higher complication rate due to a higher puncture/insertion force and/or a curved shape with more frequent posterior perforation.  Placement of a commercial device may take longer than the traditional surgical cricothyrotomy.  The use of one commercial cricothyrotomy device (Pertrach) is shown in Figure 4-7 (Figure Not Available) .

## Ventilation

Ventilatory parameters may be critical in preventing barotrauma and significant hypotension and in eliminating hypoxemia and hypercarbia. Animal studies suggest that the minute volume as reflected by a short inspiratory and a prolonged expiratory phase is an important parameter.

*Bag-valve devices should not be used for ventilation* of adults or children unless a large catheter (3 mm ID) has been passed. The clinician should verify that adequate tidal volumes are being delivered with this technique by monitoring for hypoxemia.

**Procedure**

The actual technique of needle cricothyrotomy with translaryngeal jet ventilation is fairly simple (Fig. 4-8) . The anatomy, landmarks, and several of the steps in the technique are identical to that for surgical cricothyrotomy (see Figs. 4-1 and 4-3) .

---

**TABLE 4-9** -- Commercial Devices

**Commercial Cricothyroidotomy Devices**

There are many commercial cricothyrotomy devices. A few of them are listed below. Mention is not intended to imply endorsement of these devices.

1. NU-TRAKE and PEDIA-TRAKE are distributed by International Medical Devices, Inc., PO Box 408 Canoga Park, 19355 Business Center Drive, Suite 8, Northridge, CA 91324, or PO Box 408 Canoga Park, CA 91305; phone (818) 701-5433 or (800) 522-LIFE (outside California)

2. Pertrach: Pertrach, Inc., 900 Davisson Run Rd, Suite 301, Clarksburg, WV 26301, phone (304) 624-7122 or (800) 736-3194

3. Abelson cricothyrotomy cannula: Gilbert Surgical Instruments, 115 Harding Ave, PO Box 458, Bellmawr, NJ 08031, phone (609) 933-2770

4. Quick Trach emergency cricothyrotomy device for adults and infants: VBM Medizintechnik GMBH, D-7247 Sulz am Neckar, Germany, phone (07454)6211; telefax (07454)4953

5. Portex Mini Trach Kit

| |

| 6. Melker emergency transcricothyrotomy catheter set: Cook Critical Care, PO Box 489, Bloomington, IN 47402; phone (800) 457-4500 |
| **Commercial Transtracheal Puncture Devices** |
| Also designed for transtracheal puncture, the Trans-Cricothyrotomy device is distributed by VBM Medizintechnik (same address and phone as above) |
| **Commercial Manual Ventilator Devices** |
| 1. Manual valve that allows for the flow of oxygen when the control button is pushed. Manual Valve, by Instrumentation Industries, Bethel Park, PA |
| 2. Manujet: a manual jetting device by VBM Medizintechnik GmbH, Bruhlstrasse 10, 0-727 Sulz am Neckar, Germany |

A small 3- to 5-mL syringe containing 1 to 2 mL of sterile normal saline or water is attached to a large-bore needle (13 or 14 ga). If lidocaine will be injected, then 1 to 2 mL of 1% lidocaine without epinephrine should be in the syringe. If the patient is responsive, 1 to 2 mL of lidocaine may be injected into the larynx to prevent reflex coughing when the needle or cannula enters the larynx.

While the dominant hand (usually the right) holds the syringe, with the needle directed caudally at less than 45° to the skin, the other hand (nondominant) holds and stabilizes the larynx. The thumb and middle fingers of the nondominant hand stabilize the cricoid cartilage, and the index finger palpates the cricothyroid membrane.

The needle is inserted through soft tissues, the skin, and the cricothyroid membrane (see Fig. 4-8) . While negative pressure is exerted on the barrel of the syringe, the needle is inserted through the cricothyroid membrane into the larynx. Air bubbles in the fluid-filled syringe signify entry into the larynx. After entering the larynx, the cannula is advanced into the larynx, and then the needle is removed. The cricothyroid membrane should be punctured in the inferior aspect (i.e., nearer the cricoid cartilage than the thyroid cartilage) to avoid the cricothyroid arteries (see Fig. 4-3 *A*).

If there is much resistance to the needle's or catheter's passage through the skin,

subcutaneous tissue, or cricothyroid membrane, kinking or bending of the catheter may occur unless a stiffer catheter is used. A small nick in the skin may be needed to facilitate passage through the dermis into the subcutaneous tissue. A percutaneous dilatational or Seldinger technique may result in fewer complications. [103] [104]

The cannula is secured by suturing it to the skin or by placing a circumferential tie around the neck. The oxygen source is connected to the cannula. It is critical that the proximal end of the cannula be snug or tightly fitting and securely held around the puncture wound opening. If it is not securely held in place, subcutaneous emphysema will result and/or the cannula may be dislodged from the larynx. A trial of several bursts of oxygen flow is recommended to make certain that the cannula is correctly placed and the setup is working and ventilating properly.

The hypoxic patient should receive 100% oxygen in intermittent bursts <50 psi at a rate of 20 bursts per minute. For children, 30 psi has been recommended. The percentage of inspired oxygen concentration can then be adjusted, depending on blood gas results. The inspiratory phase or insufflation with the burst of oxygen should last approximately 1 second, and the expiratory phase long enough to allow for adequate exhalation (2 to 9 seconds has been suggested).

**Precautions**

The location of the needle puncture (or incision) in the skin and cricothyroid membrane is critical. The preferred location is near the midline in the inferior aspect of the cricothyroid membrane, just above the cricoid cartilage. The needle (or scalpel) is directed at an approximately 45° angle to the skin in a caudal direction. The key landmarks in the neck should be identified before inserting the needle-cannula combination into the cricothyroid membrane.

Too small an opening in the cricothyroid membrane leads to hypoxemia, hypercapnia, and respiratory acidosis. In an adult, a 13- or 14-ga needle or larger bore with a 3-mm ID is needed to provide an adequate-sized opening.

Use of a bag-valve device or a demand valve resuscitator apparatus to ventilate a patient through a translaryngeal cannula is generally inadequate. Using a 50 psi oxygen source, up to 89 L/min can be delivered through a 13-ga cannula, and up to 72 L/min can be delivered through a 14-ga cannula. [87] Additional side holes or ports in the cannula to allow for the additional egress of oxygen into the trachea and to limit the obstruction of the cannula by mucus plugs are desirable.

During the insufflation phase of percutaneous translaryngeal ventilation, secretions in the upper airway are blown out of the mouth and nose. It is recommended that personnel stand clear of the patient's face to avoid being sprayed with secretions when oxygen exits through the patient's glottis and pushes oropharyngeal secretions out the glottis and then out the nose and mouth. This may be a useful side effect if partial upper airway obstruction is present, as with a foreign body (e.g., a bolus of meat or a peanut), because some of the delivered volume of air exiting through the patient's glottis might dislodge such a foreign body. The risk of aspiration is decreased or eliminated by

lowering the head. The proximal end of the cannula should be snug against the puncture wound to minimize localized subcutaneous emphysema and should be secured in place to prevent the cannula from being dislodged.

## Complications

The exact incidence of complications with percutaneous translaryngeal ventilation is not known, but it is thought to be low, considering that the complication rate of translaryngeal puncture alone is in the range of 0.03 to 0.8% (Table 4-10) . [105]

Bleeding can occur at the site of the needle puncture, but this is usually not a major problem. Hemoptysis may occur but is infrequent. Fatal hemorrhage secondary to transtracheal aspiration for sputum cultures has been reported, [50] although no bleeding fatalities secondary to percutaneous transtracheal ventilation have been reported.

Minor bleeding is the most common complication of a surgical cricothyrotomy, whereas subcutaneous emphysema is the most frequent complication of percutaneous translaryngeal ventilation. With percutaneous translaryngeal ventilation, subcutaneous emphysema will occur if egress of gas is prevented by inadequate exhalation (e.g., with occlusion of the mouth and nose or with inadequate cannula size). The development of subcutaneous emphysema with percutaneous transtracheal ventilation is often immediate and dramatic. If this complication does occur, the subcutaneous emphysema may be gently squeezed away from the midline and the trachea can often be recannulated and successfully ventilated. Subcutaneous emphysema can be decreased or avoided by making sure that the flange or hub of the cannula fits securely against the skin.

Barotrauma secondary to high airway pressures may occur if percutaneous translaryngeal ventilation is used when complete airway obstruction is present. Such barotrauma could lead to serious complications, including pneumothorax, pneumomediastinum, and subcutaneous emphysema.

Another side effect that can occur in the conscious patient is coughing with each burst of oxygen. A few milliliters

---

**TABLE 4-10** -- Complications of Percutaneous Translaryngeal Jet Ventilation

Common
   Subcutaneous emphysema--most common (less occurrence if there is a "secure" fit at the skin)
   Kinking of the catheter
   Blockage or obstruction of the catheter
   Coughing (in a conscious patient)
Infrequent
   Bleeding (minor), hematoma
   Infections
   Aspiration
   Incorrect or unsuccessful catheter placement
   Prolonged procedure time
   Persistent stoma
   Subjective feeling of a "lump in the throat"
   Pneumatocele
Serious, rare complications
   Barotrauma (secondary to high airway pressures, more common with complete airway obstruction)
   Pneumothorax
   Pneumomediastinum (less occurrence if high airway pressures are avoided, and not performed with complete airway obstruction)
   Mediastinal perforation
   Esophageal perforation
   Dysphonia or voice changes (secondary to vocal cord injury, laryngeal fracture, or disruption of laryngeal cartilage)
Potential or theoretical complications (not yet commonly associated with percutaneous translaryngeal jet ventilation, although reported with tracheostomy and other airway procedures)
   Subglottic/glottic stenosis
   Tracheoesophageal fistula
   Damage to laryngotracheal mucosa (such as tracheobronchitis)
   Swallowing problems

of lidocaine may be injected into the larynx to help prevent coughing when the cannula enters the larynx. The initial instillation of lidocaine solution will precipitate a brief coughing episode, but further coughing should be minimized. However, because the patient undergoing cricothyrotomy in the emergency department is almost always critically ill and is rarely conscious, coughing is usually not a problem.

Percutaneous translaryngeal ventilation for an extended period of time can dry the membranes of the airway unless appropriate humidification is obtained. Techniques or devices for humidification are available. [106]

One complication that may occur with needle cricothyrotomy is kinking of the catheter as it enters the neck. This problem can be overcome if a stiffer catheter is used. A 14-ga

(1¼ inch) catheter or any device approximately 2 cm long from the hub or flange of the cannula has been recommended as the best length, because it puts the tip of the catheter in the middle or midstream of the airway.

Infection, ranging from cellulitis, perichondritis, or laryngotracheitis, is a possible complication of percutaneous translaryngeal ventilation, but it has not been reported in most series. Careful technique and follow-up care should help prevent these complications of infection and obstruction by blockage of the tube.

Damage to the laryngotracheal mucosa, including necrotizing tracheobronchitis, from percutaneous translaryngeal ventilation is a theoretical complication that has not been reported. Most studies have concluded that percutaneous translaryngeal ventilation or high-frequency jet ventilation may be performed "without undue risk of tracheobronchial injury." [107]

Blockage or obstruction of the tube from bleeding or from a mucus plug occurs infrequently, although such blockage can cause acute airway obstruction. Additional small holes near the tip of the catheter may help to prevent this problem.

A pneumatocele caused by incorrect needle placement is a rare and benign complication that can be treated by aspiration with a needle. Misplacement of the cannula can lead to tracheal, mediastinal, or esophageal perforation if the needle is advanced too far. Other complications that occur with surgical cricothyrotomy could occur with needle cricothyrotomy, such as damage to the laryngeal cartilage, which may cause dysphonia or voice changes.

## CONCLUSION

Cricothyrotomy, is a simple, reliable, rapid, and effective means of achieving airway control and ventilation. It has relatively few complications. The value of cricothyrotomy as a life-saving procedure in emergency situations has been clearly demonstrated, and its usefulness has been well established in emergency care. Both surgical cricothyrotomy and needle cricothyrotomy with translaryngeal jet ventilation can be used for an extended period of time if appropriate ventilation factors are maintained. Cricothyrotomy has also gained acceptance as an elective procedure for surgical access to the airway. In many instances, cricothyrotomy is the airway procedure of choice.

# Chapter 5 - Tracheostomy Care and Tracheal Suctioning

**Steven M. Joyce**

## TRACHEOSTOMY CARE

The key to optimal routine tracheostomy care is cleanliness, which keeps the tracheostomy tube free of obstruction. Tube changes are done routinely but also may be necessary in an emergency. The emergency physician should be alert for late postoperative complications such as tube obstruction or displacement, false passage, hemorrhage, infection, tracheal stenosis, and tracheoesophageal fistula. In this chapter, several procedures are discussed that may be useful to the emergency physician when a complication is recognized.

Tracheostomy, one of the oldest operations described in the medical literature, is used when long-term mechanical ventilation or control of airway secretions is indicated. It is also performed occasionally for relief of upper airway obstruction, especially in children. [1] The procedure is usually performed in the operating room and occasionally at the bedside. Complications requiring emergency management, although infrequent, can occur in both the early and late postoperative periods. The emergency physician is most likely to encounter complications occurring during the latter period and should be familiar with the equipment and techniques for handling tracheostomy-related emergencies.

Tracheostomy tubes are made of many materials, including metal, Silastic, Teflon, polyethylene, and rubber. They may be cuffed or uncuffed and may have a single lumen or a removable inner cannula (Figs. 5-1 (Figure Not Available) and 5-2) . A removable blunt-end obturator may be used to aid passage. The inner cannula is a removable tube that fits snugly inside the tracheostomy tube itself. Normally the patient breathes through the inner cannula; the cannula can be removed daily for cleaning (which is usually performed with hydrogen peroxide and water), thereby lessening the buildup of mucus in the tracheostomy tube. Tubes may be curved, angled, or flexible. [2] Although it is important that the emergency physician recognize the type of device in place, the basic and emergency care of the tracheostomy itself is relatively independent of the type of tube used.

### Routine Tracheostomy Care and Changing a Tracheostomy Tube

The most important factor in keeping a tracheostomy tube functioning is the control of mucus to maintain the patency of the tube or inner cannula. If humidified air is inhaled, mucus remains liquid and generally is expelled freely by coughing. The use of intermittent humidified air at home may minimize inspissation of mucus in the trachea and cannula. When mucus is excessive, suctioning is performed as often as needed to clear secretions and is usually done by the patient or family. The technique for suctioning through a tracheostomy tube is described later in this chapter. Clearing of

inspissated secretions may be aided by instillation of 5 to 10 mL of sterile saline.

Once the tracheostomy wound has matured, generally at about 5 days after surgery, routine changing of the tracheostomy tubes can be carried out safely and is necessary to clean the tubes satisfactorily. This is usually done by the patient or family on an as-needed basis, generally about every 2 weeks. Emergencies may also occasionally require changing of the tracheostomy tube.

## Equipment and Setup

Before changing the tracheostomy tube, the new tube should be carefully checked. It should be the same size, and preferably the same type, as the tube being removed. Size is usually marked on the tube or neck plate and usually reflects the inside diameter in millimeters. All component parts should fit together easily, and when a cuffed tube is placed, the cuff should be tested under pressure. Once this has been accomplished, the patient is positioned *with the neck hyperextended*, when possible. Adults may sit or lie down. Children should be lying down with a rolled towel under the shoulders, and held firmly. Some patients may require soft hand restraints during the changing procedure. Because breath holding or coughing may occur during the procedure with resultant hypoxia, it is optimal to provide supplemental oxygen through the existing tracheostomy tube prior to the procedure. However, patients with near total obstruction require immediate relief of the obstruction, as discussed later in this chapter.

## Technique

The patient's tracheostomy tube should be removed in a single sweeping motion, and the new tube, which has been prepared with the obturator in position and lubricated, should be gently inserted during inspiration into the stoma with the same sweeping circular motion. No force should be exerted, because creating false passages is deceptively easy and may prove disastrous. The tube may also be changed by using a removable obturator or over a catheter using a modified Seldinger method, which greatly reduces the chance of creating a false passage (Fig. 5-3) .

Once the tracheostomy tube is in position, the obturator is removed, and the inner cannula (if needed) is placed. Proper position is confirmed by good airflow and breath sounds with inspiration and expiration. The tracheostomy tube should be tied snugly around the patient's neck with tracheostomy tape while the head is held in flexion. The tape should be touching the skin around the neck with nothing intervening. Slight tension should be felt as a finger is passed under the tape. If an inner cannula is being used, the patient should be instructed on how it can be removed for cleaning. Furthermore, the patient should be encouraged to remove it for cleaning as often as necessary to keep it mucus free.

## Complications of Tracheostomy

### Obstructed Tracheostomy Tube

A tracheostomy patient who presents with respiratory distress should be *assumed to have a partially or completely obstructed tracheostomy tube*. Such patients should immediately be placed on high-flow humidified oxygen, with the flow directed either at the tracheostomy tube or over the mouth, whichever has the best airflow. The usual cause of obstruction is inspissated mucus. Obstruction usually occurs in the inner cannula or tracheostomy tube itself, although more distal tracheal plugging can also occur.

If an inner cannula is present, it should be removed so it can be cleaned and obstructing plugs removed. If a cannula is not present, immediate suctioning is appropriate in an attempt to clear the tracheostomy tube. If suctioning is not successful, 5 to 10 mL of sterile saline should be injected into the trachea and suctioning repeated. This loosens mucus and stimulates coughing, often enough to dislodge a large obstructing plug. If suctioning and removal of the inner cannula do not immediately clear the airway obstruction, the entire tracheostomy tube should be removed and replaced with a new tube. [4] In an emergency, one should not hesitate to remove a tracheostomy tube, because most patients are able to breathe easier through a stoma than through a partially blocked tube. The tube may then be replaced as described above, using a catheter or flexible laryngoscope as a guide. [3]

Persistent respiratory distress despite a successful tube replacement should lead to a search for other etiologies (e.g., low tracheal stenosis, pneumonia, aspirated material). Oral endotracheal intubation should be considered if the physician is unable to replace the tube in a ventilator-dependent patient.

**Displaced Tube and Stomal Closure**

A tracheostomy tube may come out during either cleaning or coughing and cannot be replaced because the stoma is closing. Even if the tube has been out for only a few hours, compromise of the stoma may have already begun. Accept the patient's judgment that the old tube will not fit. Forceful attempts to insert the same size tube or to dilate the stoma with hemostats may create false passages, bleeding, and traumatic edema, making reintubation almost impossible. The patient's tube should be inspected to identify its size, which can usually be found on the neck plate. A new tracheostomy tube one or two sizes smaller can generally be inserted with relative ease. Care should be taken to avoid false passages. Once the smaller tube has been inserted to maintain the tracheal stoma, the stoma may gradually be enlarged on a daily basis by insertion of larger tubes until a maintenance tube of appropriate size can again be worn. [5]

**False Passage**

Occasionally, when a tracheostomy tube has been removed, the proper passage for easy insertion of a new tube cannot be found. Often, simple extension of the neck will line up tissue planes and facilitate passage. False passages are easily created and can be recognized by failure of positive-pressure ventilation to inflate the lungs and rapid development of subcutaneous emphysema. Use of a catheter as a guide prior to removal of the old tube should prevent this complication. A catheter or laryngoscope

also can be inserted into the stoma and the new tube advanced over it (see Fig. 5-3) . [5]

**Hemorrhage**

After the immediate postoperative period, bleeding from a tracheostomy should be considered a life-threatening emergency until proven otherwise. A tracheoinnominate fistula has been reported in up to 4.5% of tracheostomies and is most common between 1 and 3 weeks postoperatively. [6] The fistula is caused by erosion from an improperly fitted or placed tube, a low tracheotomy site, or an overinflated cuff. This life-threatening complication may be preceded by coughing of more than 10 mL of blood from the tube or noticeable pulsating tube movement. Death is by exsanguination or asphyxiation from aspirated blood and occurs in more than 86% of cases with this complication. [7]

If premonitory bleeding and hemoptysis occurs, the patient should undergo prompt bronchoscopy with the tube removed to inspect the tracheal mucosa and identify the bleeding site. When massive hemorrhage occurs and a tracheoinnominate fistula is suspected, the tube cuff should be overinflated to apply pressure from inside the trachea. If significant hemorrhage continues, digital pressure may be applied simultaneously over the skin of the suprasternal notch, or a gloved finger can be inserted through the skin incision and into the pretracheal soft tissues to compress the artery. [7] [8] Digital pressure is maintained until emergency sternotomy can be performed and the vessel ligated.

Minor bleeding (i.e., <10 mL) at the stoma may be due to minor trauma during tube insertion. If visual inspection clearly identifies a superficial bleeding site, it may be packed or cauterized.

**Infection**

Bacterial contamination of the granulating stoma invariably occurs, but infection is uncommon. Early peristomal cellulitis is treated with oral antibiotics and close follow-up. Paratracheal abscess requires prompt drainage and intravenous antibiotics to prevent mediastinitis. Necrotizing infections around the stoma are rare and are treated by prompt removal of the tracheostomy tube, placement of an oral or nasal endotracheal tube, and aggressive debridement and antibiotic therapy. [6]

**Tracheal Stenosis and Malacia**

Overinflation of the tracheostomy tube cuff may result in pressure necrosis of tracheal tissues, which may subsequently result in tracheal stenosis or malacia. Symptoms usually develop several weeks or longer after decannulation but may become apparent while the tube is still in place. Initially the patient may complain of dyspnea on exertion, chronic cough, or inability to clear secretions. As obstruction progresses, dyspnea at rest and stridor may develop.

Initial treatment for partial obstruction with the tube in place, as described above, should be attempted but is unlikely to afford improvement. If the patient has been

decannulated, the stoma will be closed or nearly so, and endotracheal intubation will not be likely to bypass the narrowed segment, which is several centimeters below the stomal site.

The patient's head should be elevated and humidified supplemental oxygen provided. Nebulized racemic epinephrine and parenteral steroids have been suggested. [7] Plain radiographs may not be helpful. Diagnosis is made by bronchoscopy, and dilation or stenting may be attempted during this inpatient procedure. Definitive treatment is surgical resection of the stenosed or weakened section and tracheal reconstruction.

**Tracheoesophageal Fistula**

Development of a fistula between the trachea and esophagus in the postoperative period is rare and is usually due to pressure on the membranous trachea by an overinflated cuff or poorly positioned tube. Increased secretions and coughing after oral feeding are the common presenting symptoms. Aspiration of food or gastric contents may cause pneumonia or pneumonitis. Gastric distention may be noted in ventilated patients. Mediastinitis may develop.

Treatment is surgical repair, as these fistulae do not close spontaneously. Repair may be deferred until positive-pressure ventilation is no longer needed, although a feeding gastrostomy is necessary in these cases. [7]

**Conclusion**

Knowledge of the basic types and routine care of tracheostomy tubes, as well as the scope of postoperative problems, should allow the emergency physician to deal confidently with emergent complications of tracheostomy.

# TRACHEAL SUCTIONING

Tracheal suctioning removes secretions, aspirated material, or both from the airways of patients whose cough reflex has failed or is bypassed by an artificial airway. Removal of secretions prevents atelectasis, improves gas exchange, and helps eliminate infected material. Secretions obtained by suctioning also may be useful in diagnosis of pulmonary infections. With minimal training, the procedure may be

performed by respiratory therapists, nurses, or physicians. Although tracheal suctioning may be performed easily at the bedside, there is a potential for serious complications, so proper precautions must always be taken.

Tracheal suctioning has been practiced since the introduction of positive-pressure ventilation in the 1950s as a method of removing tracheobronchial secretions. The technique remains vitally important for the maintenance of proper gas exchange in

endotracheally intubated patients and in selected patients whose cough reflex is otherwise impaired. The development of new catheter materials has resulted in catheters with various diameters and tip designs that minimize mucosal injury and allow selective bronchial catheterization. Other features, such as concomitant oxygen delivery with in-line systems, permit secretion removal while minimizing hypoxemia.

**Indications and Contraindications**

The following discussion refers principally to tracheal suctioning through an endotracheal or tracheostomy tube. Nasotracheal suctioning is discussed separately.

The basic indications for tracheal suctioning are the need to perform bronchopulmonary toilet in intubated or obtunded patients and to sample lower respiratory tract secretions for diagnostic tests (when coughed specimens are inadequate or cannot be obtained). In an emergency setting, tracheal suctioning is usually performed immediately after endotracheal intubation to clear the airways of aspirated materials or accumulated secretions.

Bronchopulmonary toilet is indicated when secretions are visible at the endotracheal tube orifice; when auscultation of the lungs reveals coarse rales, rhonchi, or tubular breath sounds; or when the sudden onset of dyspnea or arterial oxygen desaturation occurs in patients at risk for lower airway occlusion. Those at risk include all patients with artificial airways (which make coughing ineffective), especially those patients with bronchopulmonary infections and excess secretions.

Most authors agree that "routine" suctioning is unwarranted and potentially dangerous; the procedure should be performed only on an as-needed basis when the previously mentioned indications exist. [9] [10] [11] The only relative contraindication to tracheal suctioning is cardiovascular instability, which is exacerbated by the procedure, as in the patient with cardiogenic pulmonary edema and hypoxemia. However, even in such cases, when treatment of the underlying disorder is not sufficient to maintain adequate gas exchange, tracheal suctioning should be undertaken using techniques to minimize the likelihood of hypoxemia and arrhythmia.

**Equipment**

Appropriate vacuum settings for optimal secretion removal and minimal mucosal trauma have been proposed. [10] Settings of 60 to 80 mm Hg for infants, 80 to 120 mm Hg for children, and 120 to 150 mm Hg for adults are recommended. Higher settings cause turbulent flow through the catheter, which can reduce the efficacy of secretion removal and may increase tracheal mucosal injury.

Catheters made of polyvinyl chloride are most commonly used. They are flexible; require no lubrication; and are translucent, allowing visualization of secretions. [9]

The external diameter of the suction catheter should be approximately one half the internal diameter of the endotracheal tube. [11] Larger catheters may prevent adequate

airflow into the airways during suctioning, and the resultant evacuation of gases may result in atelectasis and hypoxemia. However, in the setting of life-threatening airway obstruction, the largest catheter that will fit the airway should be used. Smaller diameter catheters may not remove secretions effectively.

Catheter tip designs vary depending on the intended use. Conventional catheters with an end hole and several side holes are the most commonly available types in an emergency department setting. Tips designed for specialized uses exist but offer no great advantages for uncomplicated tracheal suctioning. Catheters designed for selective bronchial suctioning are seldom used in an emergency situation. A closed in-line system that does not require interruption of the ventilator circuit has been developed for use in ventilated patients who have unstable cardiovascular conditions or are dependent on positive end-expiratory pressure (PEEP). [11] Use of such a closed system has been shown to reduce the incidence of both hypoxemia and arrhythmia during suctioning. [12]

A cardiac monitor and, if available, a pulse oximeter should be attached prior to the procedure. Standard resuscitation drugs and equipment should be immediately available.

**Procedure**

The clinician should assemble all equipment and ensure that it is functioning properly.

Aseptic technique should be used as much as possible. Hands are washed with antimicrobial soap, and a sterile glove is used to manipulate the suction catheter. In emergencies, asepsis may not be practical, but one should try to minimize contamination of the airways.

The clinician should preoxygenate the patient by delivering 6 to 7 breaths of 100% oxygen either by handheld bag or ventilator. However, many ventilators will not deliver an $Fi_{O2}$ of 1.0 for up to 2 minutes after the setting is changed. [10]

Immediately after preoxygenation, introduce the sterile catheter into the endotracheal tube with the gloved hand, taking care *not* to occlude the vacuum vent during insertion. Pass the catheter tip past the distal end of the artificial airway until resistance is met (usually at the carina). Pull the catheter back slightly before applying suction. Then occlude the vent to apply suction and rotate the catheter in a circular motion around the tube lumen while slowly withdrawing it from the airway.

This entire procedure should interrupt the patient's ventilation for only approximately 20 seconds, with the catheter actually in the airway for <15 seconds, to minimize hypoxemia and atelectasis. [11]

Immediately after the procedure, the patient should be reoxygenated using a combination of hyperoxygenation, hyperventilation, and hyperinflation. Hyperoxygenation is achieved by delivering an $Fi_{O2}$ higher than the patient's

maintenance value (generally 100% oxygen is used). Hyperinflation is achieved by delivering up to 1.5 times the usual tidal volume, again as estimated either by bag ventilation or by using the ventilator sigh function. A clinical study by Baun and an exhaustive review by Barnes and Kirchoff support

the combination of these techniques to minimize postsuctioning hypoxemia and its attendant complications. [13] [14]

Thick secretions may be difficult to remove. In these cases, 5 to 10 mL of sterile normal saline should be injected into the artificial airway, after which several deep breaths should be delivered by bag or ventilator just before suctioning. After the procedure, $Fi_{O2}$ and other ventilator settings should be returned to presuctioning values. Clotted blood or other thick secretions not removed by suctioning may be retrievable by extraction with a No. 6 Fogarty catheter. [15] [16] The catheter is passed beyond the occluding material and then inflated. The material is pulled ahead of the catheter during its withdrawal.

Secretions for microbiologic studies may be obtained using a sterile mucus trap. The specimen is transported in the sealed trap for prompt processing.

**Complications**

As with most invasive procedures, tracheal suctioning is not without the potential for serious complications. Fortunately, most can be prevented or minimized.

Difficulty in passing a suction catheter may be due to the patient biting on the endotracheal tube, airway kinking, inspissated secretions, herniation or rupture of the cuff balloon, tube malalignment, or placement of the tube outside the trachea. Solutions to these problems include placement of a bite block; removal of redundant endotracheal tube length to prevent kinking; injection of saline down the tube to loosen secretions; and prompt replacement of blocked, malfunctioning, or malpositioned tubes.

Hypoxemia, although transient, is perhaps the most serious complication of tracheal suctioning, as it can lead to life-threatening cardiac dysrhythmias. Inadequate oxygenation before or after suctioning, prolonged suctioning (i.e., more than 15 seconds), and excessive catheter size are the most common causes. Hypoxemia may be presumed when dysrhythmias develop during or just after the procedure. Dynamic oxygen saturation measurement with a pulse oximeter may prove helpful. Fortunately, hypoxemia may be prevented or minimized by proper oxygenation techniques, as described above. If available, some suction catheters allow alternating or simultaneous oxygen delivery through the catheter itself during the procedure. [17] [18] If the patient is ventilator dependent, a closed in-line suction system has been shown to reduce hypoxemia during this procedure. [12]

Dysrhythmias may be caused by hypoxemia, as discussed previously, as well as by tracheal irritation. When the mucosa is irritated by the suction catheter, both vagal and sympathetic afferents may be stimulated. Vagal stimulation may produce bradycardia with resultant hypotension, whereas sympathetic stimulation can precipitate

tachydysrhythmias or even ventricular fibrillation, especially when hypoxemia is present. The incidence of dangerous dysrhythmias during suctioning is unknown, but they are probably not rare. Shim and coworkers described significant dysrhythmias (some persisting for 2 minutes) that occurred in 6 of 17 patients undergoing suctioning while breathing air; all dysrhythmias were abolished when the patients breathed 100% oxygen for 5 minutes before undergoing the procedure. [19] In patients subject to bradycardia during suctioning, both nebulized and parenteral atropine were effective in preventing this arrhythmia. [20] Thus, attention to cardiac monitoring and oxygen saturation during and after suctioning is very important. Suctioning should be terminated immediately when dysrhythmias (other than preexisting dysrhythmias or sinus tachycardia) are observed, and oxygenation should be provided as previously described.

Intracranial pressure (ICP) may increase transiently during tracheal suctioning, which leads to theoretic concerns in patients whose cerebral perfusion pressure is already marginal. Rudy and colleagues reviewed a number of studies examining this transient ICP elevation; none were found to demonstrate a clinically significant deleterious effect in the patients studied. [21] They also reviewed studies that examined the efficacy of pretreatment with various drugs to prevent increases in ICP with tracheal suctioning. No significant effect of lidocaine, fentanyl, thiopental, or succinylcholine in abating the ICP increase with suctioning was demonstrated, with the exception of intravenous lidocaine (1.5 mg/kg) in patients receiving concurrent pentobarbital therapy. Other studies of patients with head injuries who had baseline elevations in ICP suggest that the cough reflex is the predominant cause of ICP rise with suctioning in the unanesthetized and nonparalyzed patient. Both intravenous lidocaine (1.5 mg/kg) and intratracheal lidocaine (2 mL of a 4% solution) administered before suctioning or temporary paralyzation attenuated ICP increases during suctioning in patients with severe head injuries. [22] [23] However, for patients without signs of elevated ICP, routine pretreatment with drugs to prevent transient ICP increases is probably unnecessary.

Tracheal mucosal injury is a frequent complication of tracheal suctioning. Some degree of irritation accompanies even properly performed suctioning, but it can be minimized. Catheters of soft polyvinylchloride should be chosen, and appropriate suction settings should be used. Suctioning should be performed no more frequently than indicated, because mucosal damage occurs more often in the absence of secretions. Tracheitis may occur as the result of frequent or improperly performed suctioning; it can be recognized by a persistent hacking cough and blood-streaked secretions. Tracheitis may be treated by instilling 1 mL of 1% lidocaine every 2 to 4 hours as needed and by reducing the frequency of endotracheal suctioning. [11] Using appropriate technique and vacuum settings should further minimize tracheal irritation during suctioning.

Atelectasis has been reported as a complication of suctioning and is thought to be related to the diameter of the suctioning catheter, the suction setting, and the duration of suctioning. Atelectasis can best be avoided by proper selection and use of materials for suctioning and can be treated by postprocedural hyperinflation, as described. Prevention and prompt treatment of atelectasis will reduce the chances of suction-induced hypoxemia.

Bronchoconstriction may result from mechanical airway irritation. Cessation of the

procedure, institution of positive-pressure ventilation, and use of bronchodilators as needed should bring about resolution of this complication.

Sudden death has been reported during tracheal suctioning and is probably due to one or more of the complications discussed earlier. For this reason, cardiopulmonary resuscitation equipment and resuscitative drugs should always be close at hand before the procedure is begun.

## Interpretation

Successful tracheal suctioning is evidenced by clearing of rhonchi or rales, relief of dyspnea, improvement of oxygenation

(when monitored), and removal of visible secretions. The procedure should be repeated only if indications remain.

## Nasotracheal Suctioning

Nasotracheal suctioning is an infrequently used procedure that is technically more difficult to perform than suctioning through an endotracheal tube and potentially more hazardous. [9]

### Indications and Contraindications

Nasotracheal suctioning is reserved for patients who require assistance in clearing secretions because of partial airway obstruction, impaired cough reflex, or excess secretions. Many would argue correctly that these are sufficient indications for endotracheal intubation. However, rare instances may occur in which nonintubated patients require tracheal suctioning. An example is the patient with chronic emphysema who refuses intubation but whose cough is insufficient to clear the excess secretions produced by an intercurrent bacterial bronchitis.

### Procedure

The materials used for this approach are the same as those used for tracheal suctioning, with the addition of a water-soluble lubricant for easier passage of the catheter through the nose. The patient is best positioned in the "sniffing position" as described for nasotracheal intubation.

As the catheter is advanced through the nasopharynx, airflow sounds are monitored through the unattached proximal catheter opening. The sounds increase as the distal tip approaches the glottis. Gentle, rapid advancement of the catheter during inspiration should allow the tip to pass into the trachea. Successful tracheal placement is signified by a vigorous cough and the inability of the patient to phonate much above a whisper. If the catheter instead enters the esophagus or valleculae, airflow sounds are lost, no

cough is produced, and the patient may gag or swallow.

After successful tracheal placement, the clinician should reoxygenate the patient with the catheter in place by allowing several deep breaths of 100% oxygen before suctioning. Then the catheter should be attached to the suction source at the appropriate setting, the tip advanced to about the level of the carina, and the suction port occluded and the trachea suctioned as discussed earlier, with care taken to ensure reoxygenation following the procedure.

### Complications

All of the complications discussed for endotracheal tube suctioning can occur during nasotracheal suctioning. In addition, nosebleeds, gagging, aspiration, and laryngospasm may occur, or the operator may simply be unable to direct the catheter tip into the trachea. Because of these drawbacks, nasotracheal suctioning is seldom the procedure of choice for clearance of airway secretions, nor is it an ideal method for obtaining specimens for microbiologic study, because contamination by nasopharyngeal flora is inevitable.

## Conclusion

Tracheal suctioning is an important adjunct to bronchopulmonary toilet in patients whose cough reflex is impaired, whether by an endotracheal tube or otherwise. Although easily taught, the procedure is not without the potential for serious morbidity or even mortality. Tracheal suctioning should be undertaken only when indications exist and should be performed by trained individuals with a full appreciation of its potential complications.

## TRANSTRACHEAL NEEDLE ASPIRATION

Patients with signs and symptoms of acute bronchopulmonary infection require expeditious diagnosis and treatment. Examination and culture of lower respiratory tract secretions are desirable in these patients and are mandatory in those who are critically ill. Although expectorated sputum is always contaminated somewhat with oropharyngeal flora, properly screened expectorated sputum is a sufficient specimen in most cases. Occasionally, results of sputum examination and culture are equivocal, or an adequate specimen simply cannot be obtained. In these selected cases the emergency physician may wish to use the technique of transtracheal aspiration to obtain a specimen of tracheobronchial secretions before initiation of antibiotic treatment.

Poor correlation between cultures of expectorated sputum and those of lower respiratory tract secretions has been demonstrated. [24] Recognizing the need for uncontaminated culture specimens, Pecora introduced transtracheal needle aspiration, a modification of the technique commonly used for translaryngeal anesthesia. [25] Cultures of lower respiratory tract secretions obtained by transtracheal needle aspiration are more predictive of pulmonary infection than are those obtained from expectorated washed sputa or older bronchoscopic aspiration techniques. [26] [27] Newer

bronchoscopic methods using a protected specimen brush have improved the diagnostic accuracy of the bronchoscopic technique, although it may not be available in all hospitals or in a timely manner. [28] Transtracheal aspiration specimens have been shown to be especially useful in the diagnosis of unusual pulmonary infections, including those caused by anaerobic bacteria, tuberculosis bacilli, *Aspergillus, Pneumocystis carinii,* and hospital-acquired and partially treated pneumonias. [29]

**Indications and Contraindications**

Failure to obtain adequate expectorated sputum is the primary reason for performing transtracheal needle aspiration. Many patients with pneumonia are obtunded and are unable to produce a coughed sputum specimen. Transtracheal aspiration also may be preferred in patients in whom unusual infections are suspected.

Transtracheal aspiration should not be used when a sputum specimen that is suitable for proper diagnosis can be obtained by expectoration or when bronchoscopy is indicated. Diagnostic specimens may be more safely obtained in such cases by bronchoscopy using a protected specimen brush. [28] Absolute contraindications involve patient safety. Uncooperative patients are most likely to suffer tracheal damage and bleeding. Patients with bleeding diatheses should not be considered for the procedure. Hypoxia may predispose patients to potentially dangerous cardiac dysrhythmias. In addition, the inability to identify the proper anatomic landmarks for cricothyroid puncture should preclude use of this technique.

A relative contraindication to the use of transtracheal needle aspiration is the presence of chronic bronchitis, which may yield false-positive culture results. A severe paroxysmal cough increases the likelihood of subsequent subcutaneous emphysema. Bronchoscopy may be best in that situation.

**Equipment**

Commercially available intravenous catheter sets consisting of an introducer needle, J-wire guide, and a 15- to 20-cm length, 16- to 18-ga catheter are commonly used. A large (10- to 50-mL) syringe should be used to collect the sample. Two to 5 mL of *nonbacteriostatic* normal saline in a syringe should be available. Cardiac monitoring is desirable, and resuscitative drugs should be available.

**Procedure**

The patient, family, or both should be counseled regarding the procedure, and informed consent should be obtained. The patient's ability to suppress a cough on command should be assessed. Supplemental oxygen should be administered, and an arterial $P_{O2}$ >70 mm Hg or oxygen saturation >90% should be documented before beginning the procedure. [30]

The patient is positioned as shown in Figure 5-4 (Figure Not Available) *A*, with a pillow or rolled towel placed between the shoulder blades to allow full extension of the neck.

The neck is sterilized and draped. The operator then palpates the cricothyroid membrane, and a small intradermal weal is raised with local anesthetic directly over the membrane (Fig. 5-4 (Figure Not Available) *B*).

The catheter is introduced using a guide wire technique. The introducer needle is inserted as described in Chapter 4 (Needle Cricothyrotomy) and as shown in Figure 5-4 (Figure Not Available) *C*. Air is aspirated to confirm entry into the trachea. The J wire is advanced into the trachea, the needle removed, and the catheter advanced over the wire.

As soon as the catheter is in place, a 10- to 50-mL syringe is attached to the catheter hub, and suction is applied. A small aspirate amount is sufficient for analysis. If a specimen is not forthcoming, 2 to 5 mL of sterile, nonbacteriostatic saline may be injected and suction reapplied immediately. As soon as a suitable amount of sample is obtained, the catheter is withdrawn, and direct pressure is applied to the puncture site. The patient is instructed to avoid coughing as much as possible in the next 24 hours and should not receive therapies that stimulate coughing during this period.

## Complications

The complication rate for transtracheal needle aspiration is very low. Subcutaneous emphysema is usually confined to the anterior neck; is self-limited; and may be minimized by instructing the patient to avoid strenuous coughing and by avoiding positive-pressure ventilation, when possible, for 24 hours. Mediastinal emphysema is rare and is likewise self-limited.

Sustained hemoptysis is rare (1 to 2% of cases) and is minimized by attention to needle placement and prescreening for coagulopathies, when indicated. Digital pressure over the puncture site for 5 minutes will prevent prolonged hemorrhage in most instances. Persistent intratracheal hemorrhage has caused death from asphyxia in at least one case and is treated by placement of a cuffed endotracheal tube and correction of any coagulopathies.

Cardiac arrhythmias are probably secondary to vagal stimulation and are discussed under Tracheal Suctioning. Treatment of infections at the puncture site is discussed under Tracheostomy Care, and other complications are discussed in Chapter 4 (Needle Cricothyrotomy).

## Interpretation

If properly obtained, screened, and processed, cultures of transtracheal aspirates are highly predictive of the pathogen responsible for pulmonary infection.

## Conclusion

In the infrequent instances in which tracheobronchial secretions are not obtainable from expectorated sputum and when accurate bacteriologic diagnosis is essential to care of

the patient with suspected pulmonary infection, transtracheal needle aspiration is a relatively safe, practical method for obtaining such a sample. When one adheres to the precautions and guidelines presented herein, the procedure has low morbidity, high yield, and high diagnostic accuracy.

# Chapter 6 - Noninvasive Assessment and Support of Oxygenation and Ventilation

**William E. Baker ,Richard Lanoix , Dan L. Field , Jerris R. Hedges**

Ensuring delivery of oxygen ($O_2$ ) to the cell is the primary critical action in emergency medicine. Without $O_2$ to fuel cellular energy production, the cells ultimately falter and the organism dies. Except during cardiopulmonary bypass, tissue perfusion is dependent on an adequate inspired $O_2$ content, ventilatory effort, alveolar gas exchange, blood $O_2$ carrying capacity, and cardiac output. This chapter covers emergency department (ED) assessment of spontaneous ventilation and $O_2$ delivery, noninvasive means of improving inspired $O_2$ concentration and spontaneous ventilation, and delivery of inhalant medications for the treatment of reactive airway disease.

## BACKGROUND

Respiratory illness has been poorly understood until recent times. The Talmud, the ancient law book of the Israelites, blames the etiology of asthma-like illness on a malignant spirit. Later, Celsus (A.D. 25), an encyclopedist of the late Roman period, noted a favorable prognosis for a respiratory illness if the "expectoration is white as if mucus from the nose, but unfavorable if sputum is purulent, and accompanied by fever," descriptions that are consistent with chronic bronchitis and pneumonia. Celsus recommended bleeding, purgatives, emetics, and diuretics; this therapy was less preferable perhaps to his prescription for phthisis (tuberculosis), for which he recommended a leisurely sojourn down the Nile and drinking tea and honey. [1]

The Greek word alphasigmathetamualpha signified panting and was applied generally to difficult breathing and respiratory illness; the term eventually gave rise to the word *asthma*. The earliest comprehensive distinction between asthma and other respiratory diseases came from Aretaeus of Cappadocia, who first recognized and recorded the chronic recurrent nature of the disease. [2]

In 1698, Sir John Floyer wrote the first book devoted entirely to asthma and recorded the first description of pulsus paradoxus. Atropine therapy began in England in 1802, and in 1830 John Eberle deduced that "it is highly probable, therefore, that asthma consists essentially in a peculiar irritation of the pneumogastric nerves (vagus), in consequence of which the smaller bronchial tubes and air-cells are thrown into a state of spasmodic constriction." [3]

The American Thoracic Society statement on asthma in 1962 is an often-quoted definition of the disease: "asthma is a disease characterized by an increased responsiveness of the trachea and bronchi to various stimuli and manifested by a widespread narrowing of the airways that changes in severity either spontaneously or as a result of therapy." The term *asthma* is not appropriate for bronchial narrowing, which

results solely from widespread bronchial infection; from destructive diseases of the lung, as in pulmonary emphysema; or from cardiovascular disorders.

Asthma is the most common chronic disease of childhood and among the most frequent complaint of adults, resulting in 2 million outpatient visits per year; it is also the most common cause of absence from school and work. [4] Asthma, depending on one's definition, affects between 7 and 20 million people in the U.S. and is especially prevalent among those living below the poverty level. [5] The National Center for Health Statistics estimates that asthma affects 9.7 million people in the U.S. population and chronic obstructive pulmonary diseases (COPDs) afflict up to 14 million adults, with similar economic consequences. [6] Although many investigators and studies distinguish between asthma (pure reactive airway disease) and COPDs, which include chronic bronchitis (airway inflammation with increased mucus secretion) and emphysema (airway destruction and loss of airway elasticity), clinically the distinction is blurred by the similarities in ED management. In fact, the current literature cites studies that can document little to distinguish the response of either entity to bronchodilators. [7] These diseases must, however, be separated from other causes of dyspnea and respiratory distress (Table 6-1) , many of which are associated with wheezing.

## PULMONARY FUNCTION TESTING

Airway maintenance and breathing are given primacy in the ABCs of emergency medicine. Clinical assessment always

* Disease at any level of the respiratory system, central or peripheral nervous system, bellows mechanism, or heart may cause respiratoryfailure.begins with the patient's ventilatory function. The physician notes quickly the patient's mental status, level of distress, skin color, character of effort, use of accessory muscles, presence of diaphoresis, lung sounds, and vital signs. In conjunction with this clinical overview, a brief clinical history provides the physician with sufficient information on which to initiate therapy.

Unfortunately, the physician's initial clinical impression of the patient's ventilatory status is based on imprecise subjective findings that may not detect serious illness in all patients. The ability of experienced physicians to detect compromised pulmonary function when compared with pulmonary function testing seems only moderately better than chance alone. [8] In the study by Godfrey and coworkers, the sensitivity of clinical impression did not improve when the clinicians underwent training on the common and more subtle signs of respiratory distress. [8] Patients also appear superior to physicians in predicting their own pulmonary function [9] and in assessing day-to-day variation in disease, using pulmonary function testing as the standard. [10]

Regardless of the initial clinical presentation, results of treatment in a subjectively asymptomatic patient with reactive airway disease will reach, at best, only 40 to 50% of predicted normal pulmonary function and 60 to 70% when all abnormal physical signs have resolved. [11] This potentially undetected degree of dysfunction may contribute to recrudescence. Objective measures of pulmonary dysfunction serve both to quantify results of therapy and as possible predictors of admission.

Spirometry has been used for decades by pulmonary specialists to assess airway limitation. The spirometric measurements were originally validated based on comparisons with clinical and body plethysmographic data. The terminology of pulmonary function testing was derived from the various measured subsegments of spirometry (Fig. 6-1) . More recently, inexpensive handheld electronic meters have replaced formal spirometry in many clinical settings. These devices accurately measure or calculate the peak expiratory flow rate (PEFR), forced expiratory volume in 1 second

(FEV1 ), forced vital capacity (FVC), and percent FEV1 /FVC. [12] The Wright peak flow meter (Fig. 6-2) was originally designed by Wright and McKerrow for use in their pneumoconiosis unit in 1959. Subsequently, development of compact, less complex and less expensive calibrated spring-mechanism peak flow meters have allowed for widespread use in acute care and home settings (Fig. 6-3) . These peak flow meters also have been successfully used as an adjunct in the assessment of pediatric patients. In the acute clinical situation, PEFR meter readings correlate well with formal spirometry, offer simplicity, and reduce the need for patient cooperation. [13]

**Indications and Contraindications**

In the ED, acute respiratory diseases such as asthma and chronic lung diseases make up the bulk of the situations requiring the objective assessment of ventilatory status. Emergency department pulmonary function testing with either a peak flow meter or spirometer provides objective data on pulmonary status and patient response to therapy. These tests may assist the clinician in determining patient disposition [14] and may facilitate patient transfer at the time of admission by providing an objective and reproducible measure of the patient's failure to improve. Studies have found excellent correlation between PEFR and FEV1 , [13] [15] as well as between Wright and mini-Wright meters. [16] One investigation has evaluated PEFR for aiding differentiation of congestive heart failure from chronic lung disease in the patient with moderate to severe dyspnea. [17] Although opportunities will be infrequent, physicians evaluating neuromuscular diseases affecting ventilatory function, such as the Guillain-Barre syndrome, may find these techniques useful in both initial and ongoing assessment. Near respiratory arrest may be the only true contraindication to obtaining these measurements because of limited patient cooperation and delay of immediate therapy.

**Equipment**

A *spirometer* is a tube connected to a bellows-type device having communication with a recording device. The subject breathes in and out through an orifice, causing expansion and contraction of the bellows, which in turn activates the recorder that traces a curve corresponding to the lung volume. This traditional volume method is complex and cumbersome. Handheld electronic spirometers now available use sensing devices either to translate the pressure of exhalation (e.g., Respiradyne, Fig. 6-4) or to detect the number of rotations of a small turbine (e.g., Pocket Spirometer, Micro Medical Instruments, Rochester, NY) by an optical system. Both systems are self-calibrating, take little practice to use, and can calculate PEFR, FEV1 , and FVC. Some systems, such as the transducer-based Respiradyne, also give additional calculated information such as percent FEV1 /FVC and forced mid-expiratory flow rate (FEF25-75% ). Results are displayed digitally and maintained in memory until cleared.

*Peak flow meters* are simple mechanical devices that use the force of exhalation to rotate or push a membrane-coupled measuring arm or spring-loaded piston to statically record a position of maximum flow. Several brands of peak flow meters are commercially available including the Pulmo-Graph (De Vilbiss Healthcare Inc., Somerset, Pa), Assess (HealthScan Products Inc., Cedar Grove, NJ), Wright Pocket (Ferraris Medical International, Holland, NY), and the Mini-Wright (Clement Clark

International, Columbus, Ohio). Low-flow units designed for children are available.

## Procedure

The operation of peak flow meters and electronic spirometers is similar in many ways. Disposable mouthpieces are inserted or attached. If the mouthpiece is to be reused by patients sharing a common meter (during serial evaluations), the "mouth" end should be identified with pen or tape to limit the possibility of spreading infection between patients. The electronic devices must be switched on for a 30-second self-calibration period. Both the handheld spirometers and the peak flow meters can be operated with the same respiratory maneuver: a maximal inhalation followed by a maximum forced expiration into the mouthpiece. Three attempts are standard, and the highest value is recorded, provided the best two of three readings are within 10% of each other. [18] Children as young as 3 years have consistently achieved the level of cooperation necessary to perform PEFR testing. [19]

## Interpretation

Although intraindividual peak flow variability is low, [20] variability between different brands of calibrated spring mechanism peak flow meters may be significant. Flow measurements of four brands studied at low to medium flows differed by as much as 100 L/min, [21] and accuracy waned with age of the device. [22] This information should be considered when interpreting PEFR values both clinically and in the literature. Likewise, measurement of serial PEFRs should be done on the same meter. Altitude minimally affects PEFR interpretation; readings at 1400 m underestimate PEFR by 5.3 to 6.9%. [20] As with $FEV_1$ measurement, patient size affects PEFR and is most important when interpreting readings in children. Most charts of normal PEFR in pediatric patients are based on height. As age and height are also related, some investigators have developed age-PEFR charts. [14] [23] Having a measuring tape secured to the wall alongside a chart of normal values in an accessible area enables the clinician to quickly interpret the PEFR of a child. Table 6-2 lists approximate peak flow and spirometric values for various degrees of obstruction in adults and Figure 6-5 (Figure Not Available) *A* and *B* demonstrate percentile charts of PEFR vs height in boys and girls. These charts were constructed from data obtained by Carson and coworkers in 2752 healthy children in Dublin. [23] Normal PEFRs

| TABLE 6-2 -- Approximate Values for Spirometry and Peak Flow for Various Degrees of Obstruction in Adults | | |
|---|---|---|
| | $FEV_1$ (L) | $FEV_1$ /FVC (%) | Peak Flow (L/min) |

| Normal | 4.0-6.0 | 80-90 | 550-650 (males)<br>400-500 (females) |
|--------|---------|-------|-------------------------------|
| Mild | 3.0 | 70 | 300-400 |
| Moderate | 1.6 | 50 | 200-300 |
| Severe | 0.6 | 40 | 100 |

Peak flow and spirometry values vary with height, sex, and distance above sea level; men and taller persons in general have larger flow rates. The reduced barometric pressures found at higher elevations also increase airflow.

do vary in children based on a number of variables including race, geographic location, and local environment. [23] [24] [25]

The use of PEFR measurements to predict the need for admission early during emergency department treatment found that in severely compromised adults (i.e., with initial PEFRs <16% of the predicted value), an improvement in PEFR <60 L/min after the first epinephrine treatment indicated the need for admission. [26] Similarly, an initial FEV1 of 0.6 L and a post-treatment FEV1 of 1.6 L are predictive of the need for inpatient therapy. [27] PEFR values of <100 L/min initially and <300 L/min after treatment are predictive of the need for inpatient therapy in a follow-up study. [15]

These studies have been challenged due to lack of blinding. A subsequent study found that neither the initial PEFR reading nor the response to the first bronchodilator treatment was helpful in predicting admission. [28] In fact, in this double-blind study, with strict admission criteria and with the additional use of nebulized bronchodilators, <50% of those requiring admission were detected by initial measurements. However, measurements performed later in therapy, just before release, were more accurate in predicting relapse. Similarly, in a series of 83 COPD patients, a post-treatment FEV1 <40% of predicted value identified patients requiring admission (i.e., at high risk for relapse [>30%] if sent home). [29]

As with adults, initial spirometric values are weakly associated with pediatric asthma admission decisions. [30] [31] However, children with PEFRs >60% of expected *after* treatment with nebulizer therapy can be considered in the category "admission probably

unnecessary," and those with PEFRs <40% can be considered in the category "admission probably necessary." [14]

These studies indicate that when initial flow rates are extremely poor, admission is likely, because a brief course of therapy in the ED is unlikely to provide sufficient improvement. However in patients with less severe flow rates, the decision to admit should be based on the patient's response to therapy (which is dependent in part on the form of therapy and the duration of the therapy chosen). Prediction of the need for admission based on PEFR and FEV1 values obtained shortly after presentation is largely unsuccessful because of patient response variability and the option of more prolonged and aggressive ED therapy.

Hence, in adults, initially low flow rates (PEFR <100 L/min) and spirometry values (FEV1 <1.0 L) identify sick patients with the potential need for admission or close follow-up. Patients with PEFR or FEV1 values of <40% of predicted normal values after bronchodilator therapy probably require admission. Also, one can reserve blood gas analysis for patients with poor initial flow measurements or lack of improvement in pulmonary function (or hypoxia based on oximetry) and hence reduce the expense and morbidity of evaluation for reactive airway disease. [32] [33]

# PULSE OXIMETRY

Pulse oximetry has made a significant contribution to noninvasive monitoring of oxygenation in a wide variety of clinical situations. Pulse oximetry requires no special training, is noninvasive, is inexpensive, gives continuous real-time estimates of arterial saturation in the range of 80 to 100%, and provides an early warning of diminished perfusion while avoiding the discomfort and risks of arterial puncture. As a result, it has become standard of care during procedures requiring general anesthesia, [34] and it is gaining wide acceptance in out-of-hospital care, [35] neonatal and pediatric critical care, [36] adult ED care, [37] and other clinical areas. [38] [39]

**Background**

Oximetry was first developed in Germany in 1932 by Nicolai, Kramer, and Matthes. The principle of oximetry is based on the Beer-Lambert law, which states that the concentration of an unknown solute dissolved in a solvent can be determined by light absorption. Early oximeters relied exclusively on this spectrophotometric principle, using a finger or an ear as a curette containing hemoglobin, compressing these tissues to obtain a bloodless baseline absorption, and warming them to obtain a signal from maximally arterialized tissue.

Pulse oximetry, combining the principles of optical plethysmography and spectrophotometry, was invented by Aoyagi and coworkers in 1974. [40] However, it was not until 1980 that the pulse oximeter reached modern form, consisting of a probe and an onboard computer. [41] The probe, set into a reusable clip or a disposable patch, is

made up of two photodiodes producing light at 660 nm (red) and at 900 to 940 nm (infrared), and a photodetector, which is placed across a pulsatile vascular bed such as the finger or ear (Fig. 6-6) . These particular wavelengths are used because the absorption characteristics of oxyhemoglobin and reduced hemoglobin are quite different at the two wavelengths. The majority of light is absorbed by connective tissue, skin, bone, and venous blood. The amount of light absorbed by these substances is constant with time and does not vary during the cardiac cycle. A small increase in arterial blood occurs with each heartbeat, which results in an increase in light absorption (Fig. 6-7) (Figure Not Available) . By comparing the ratio of pulsatile and baseline absorption at these two wavelengths, the ratio of oxyhemoglobin to reduced hemoglobin is calculated.

Because the pulse oximeter uses only two wavelengths of light, it can only distinguish two substances. As a result, pulse oximeters measure "functional saturation," which is the percentage of oxyhemoglobin compared to the sum of the oxyhemoglobin and reduced hemoglobin. The disadvantage of functional saturation is that the denominator does not include other hemoglobin species that may be present, such as carboxyhemoglobin and methemoglobin. The advantage is that the use of only two wavelengths in the oximeter reduces device cost, size, and weight. The CO-oximeter, one example of a commercially available in vitro oximeter and the standard by which pulse oximetry is calibrated, uses four or more wavelengths, measures the "fractional saturation," and is able to measure additional hemoglobin species.

The arterial $O_2$ saturation ($Sa_{O_2}$ ) measures the large reservoir of $O_2$ carried by hemoglobin, 20 mL of $O_2$ /100 mL of blood, compared with the arterial $O_2$ partial pressure ($Pa_{O_2}$ ), which only measures the relatively small amount of $O_2$ , approximately 0.3 mL of $O_2$ /100 mL of blood, dissolved in the plasma. The $Sa_{P_2}$ correlates well with the $Pa_{O_2}$ , but the relationship is nonlinear and is described by the oxyhemoglobin dissociation curve (Fig. 6-8) . For the hypoxic patient, small changes in $Sa_{O_2}$ represent large changes in the $Pa_{O_2}$, because these $Sa_{O_2}$ values fall on the steep portion of the curve. Conversely, measurements of $Sa_{O_2}$ are relatively insensitive at detecting significant changes in $Pa_{O_2}$ at high levels of oxygenation because these $Sa_{O_2}$ values fall on the plateau portion of the curve.

Currently available pulse oximeters are accurate and precise when saturations range from 80 to 100%. [42] [43] This range is satisfactory, because for most patients an $O_2$ saturation of 80% is as much an urgent warning as one of 67%.

**Clinical Utility**

Pulse oximetry has been suggested as a fifth vital sign. [39] By providing the physician with either continuous or frequent intermittent $Sa_{O_2}$ measurements, pulse oximetry offers a more physiologic means of assessing the adequacy of oxygenation than the arterial blood gas. The latter must be drawn from an arterial source and quickly transported under specific conditions to a machine that is often distant from the patient's bedside. With pulse oximetry, the test results are available at the bedside without an invasive arterial procedure.

All recommended uses of pulse oximetry fall into one of two broad categories. First, as a

real-time indicator of hypoxemia, continuous monitoring of pulse oximetry can be used as a warning system, as many (but not all) adverse patient events are associated with arterial desaturation. [44] The second broad use of pulse oximetry is as an end point for titration of therapeutic interventions.

Although limited data address the clinical efficacy of routine monitoring of pulse oximetry in intensive care or emergency department settings, there are studies addressing operating suite and recovery room use that allow extrapolation. [45] [46] [47] These studies reported a decreased incidence and duration of desaturation episodes, fewer adverse impact events in the recovery room, and a shortened time to discovery of hypoxia. Therefore, routine monitoring of pulse oximetry in the critically ill patient population should result in fewer episodes of severe arterial desaturation and a more rapid recognition of the adverse physiologic events that produce arterial desaturation. Patient outcomes should be improved with therapeutic interventions resulting from immediate knowledge of an unfavorable $Sa_{O2}$ . [48]

## Indications

Clinical conditions where continuous monitoring with pulse oximetry is indicated are shown in Table 6-3 . Of note regarding assessment of respiratory illness severity in children, clinically unrecognized hypoxia ($Sa_{O2}$ <92%) has been documented by pulse oximetry in preschool children with respiratory symptoms. [49] Also, an initial $Sa_{O2}$ <91% in children with bronchospasm, regardless of subsequent improvement with ED management, has been associated with increased morbidity and need for admission. [50] As a "fifth vital sign," $Sa_{O2}$ monitoring affords the opportunity to assess both oxygenation and perfusion. This screen is helpful in those patients with suspected sepsis.

## Procedure

The location for the probe is determined by the clinical situation and the probes that are available. A reusable clip-on

| **TABLE 6-3** -- Clinical Applications of Pulse Oximetry |
| --- |
| During emergency airway management |
| Assess need for further airway management |

| Monitor oxygenation during interhospital and intrahospital transfer |
| Assess acute childhood asthma |
| Fifth "vital sign" |

probe makes the digits easily accessible. Little is needed in the way of preparation, and as mentioned subsequently, even nail polish may generally be left on. Other sites include the earlobe, the nasal bridge or septum, the temporal artery, and the foot or palm of an infant. Tape and splints can be used to secure the digit probe and to minimize motion.

After placement of the probe, the machine is turned on. The computer analyzes the incoming data to identify the arteriolar pulsation and displays this in beats per minute;

newer devices also display a pulse plethysmograph. Simultaneously, $O_2$ saturation is displayed on a beat-to-beat basis. Some machines have hard copy capability and can provide paper documentation of the patient's status. If the oximeter fails to detect pulsatile flow, either the reading will not be displayed or the Sa $_{O2}$ value is given with a poor signal quality warning, depending on the machine. It is valuable to evaluate serial measurements and to verify that measurements correlate with other clinical markers.

## Interpretation

Patients with good gas exchange have $O_2$ saturations between 97 and 100%. When the $Sa_{O2}$ falls below 95%, hypoxia is present, although patients with COPD may live in this range. Oxygen saturations below 90% represent relatively severe hypoxia. Children with $Sa_{O2}$ values <92% often require admission for $O_2$ and additional therapy. [49] [50] In adults and older children, as with PEFR and spirometry, a low isolated early measurement of Sa $_{O2}$ does not mandate admission because of the wide variability of response to therapy. [51] [52] However, low $Sa_{O2}$ readings should be heeded as important clinical warning signs.

Although pulse oximetry represents a significant advance in noninvasive monitoring, clinicians must recognize and understand its limitations. Pulse oximetry measures $O_2$ saturation. In comparison to arterial blood gas determination or end-tidal $CO_2$ (carbon dioxide) monitoring, which is discussed below, pulse oximetry provides no information on pH or $Pa_{CO2}$ levels, and only indirectly assesses the adequacy of ventilation. During both conscious sedation and general anesthesia, monitoring of ventilation is a more desirable goal for prevention of hypoxia. Hypoventilation and resultant hypercapnia may precede a decrease in hemoglobin $O_2$ saturation by many minutes. Furthermore, supplemental $O_2$ may mask hypoventilation and $CO_2$ retention by masking the resultant $O_2$ desaturation for which pulse oximetry monitoring is designed. Several other pulse oximeter limitations have been noted and are summarized in Table 6-4 .

### Effects of Dyshemoglobinemias

Carboxyhemoglobin results in falsely high $Sa_{O2}$ estimates of hemoglobin $O_2$ saturation. Low quantities of methemoglobin (MetHb) will reduce a pulse oximeter reading by about half the actual MetHb percentage. [53] However, even large quantities of MetHb (>10%) can result in a stable pulse oximeter reading of 85% regardless of the actual $Sa_{O2}$ . In summary, in patients with methemoglobinemia or with elevated carboxyhemoglobin levels, the reading on the pulse oximeter does not accurately depict quantitative hemoglobin $O_2$ saturation changes. [54] [55] The pulse oximeter will variably *underestimate* the percentage of abnormal hemoglobin; a CO-oximeter is required for confirmation of these conditions and quantitative analysis.

---

**TABLE 6-4** -- Factors Affecting Pulse Oximetry Readings

| |
|---|
| *Severe anemia:* Satisfactory readings obtained down to hemoglobin level of 5 mg/dL |
| *Motion-artifact:* See text regarding probe sites |
| *Dyes:* Transient effect unless methemoglobinemia results |
| *Light-artifact:* Minimize by covering probe with opaque material |
| *Hypoperfusion:* Inadequate pulse signal will be displayed |
| *Electrocautery:* Minimize by increasing the distance of the sensor from the surgical site |
| *Deep pigmentation:* Use fifth finger, earlobe, or other area of lighter pigmentation |
| *Dark nail polish:* Remove with acetone or place sensor sideways on digit |
| *Dyshemoglobinemias* (e.g., carboxyhemoglobin and methemoglobin): Falsely elevate saturation reading |
| *Elevated bilirubin:* Accurate up to bilirubin level of 20 mg/dL in adults; no problem reported for jaundiced children |
| *High saturation:* Pulse oximetry not useful for monitoring hyperoxemia in neonates |
| *Fetal hemoglobin:* No effect on pulse oximetry; falsely reduced CO-oximetry readings |

| |
|---|
| *Venous pulsations:* Artificially lower O$_2$ saturation; choose probe site above the heart |
| *Dialysis graft (A-V fistula)*: No difference from contralateral extremity unless fistula produces distal ischemia |

**Fetal Hemoglobin**

Newborn full-term infants can have up to 75% of total hemoglobin in the form of fetal hemoglobin. [56] Pulse oximeters remain accurate in the presence of fetal hemoglobin. [57] However, a CO-oximeter will erroneously interpret the carboxyhemoglobin level to be elevated, and the oxyhemoglobin level to be artificially reduced. [58] Therefore, when fetal hemoglobin levels are high, CO-oximetry readings should not be used to confirm pulse oximetric readings. It should be noted that newborns normally have up to 5% carboxyhemoglobin.

**Low Perfusion**

To function properly, pulse oximeters require a pulsating vascular bed. Hypotension with vasoconstriction, hypothermia, or the administration of vasoconstricting drugs may reduce the pulsatile component to <0.2% of the total signal. At this level, the true signal cannot be distinguished from background noise. Under these conditions, many pulse oximeters display a message indicating an inadequate pulse signal. A change in the location of the sensor to an area with higher perfusion, such as an earlobe, may improve the pulse signal. [59]

**Intravenous Dyes**

A number of dyes and pigments interfere with the accuracy of pulse oximetry. [60] [61] Methylene blue, the treatment for methemoglobinemia, absorbs light at 660 nm, similar to the absorption of reduced hemoglobin, and can artificially lower pulse oximeter saturation readings to as low as 1%. Low readings also can be seen with other intravenous dyes such as indigo carmine, indocyanine green, and fluorescein, although the rapid clearance of these agents minimizes the phenomenon. [62] [63]

**Bilirubin**

Hyperbilirubinemia does not affect the accuracy of pulse oximetry measurements. However, hyperbilirubinemia may have an effect on absorption at the lower wavelengths used by CO-oximeters, resulting in a discrepancy between pulse oximeter and

CO-oximeter readings. [64]

**Skin Pigmentation**

Pulse oximeter accuracy is somewhat reduced by deeply pigmented skin. This effect is likely due to a shift in the light-emitting diode's output spectrum as the light output is increased. This effect is small and results in only a slight decrease in accuracy over a large number of samples. [64] Placing the probe on an area of lighter pigmentation, such as the fifth finger or an earlobe, has been suggested as a means to minimize this effect.

**Nail Polish**

Conflicting data exist about the effect of nail polish on the accuracy of pulse oximeter determinations. Mounting the probe side-to-side on the finger was found to be as accurate as readings on uncovered nails. [65] This technique also circumvents the problem of only partial placement of the probe because of very long fingernails, which may cause a low $O_2$ saturation reading. An alternative solution to the problem of nail polish is to remove it with acetone.

**High Saturation**

Because the $O_2$ dissociation curve plateaus at saturation levels >90%, a large increase in $Pa_{O2}$ results in a small increase in saturation. Therefore, an error of a few percentage points could represent a large error in $Pa_{O2}$ . This is inconsequential for most adult patients but is of extreme importance for neonates at risk of retinopathy caused by hyperoxemia.

**Venous Pulsations**

Increased venous pulsations resulting from right heart failure, tricuspid regurgitation, or placement of a tourniquet or blood pressure cuff above the probe can interfere with accurate readings and lead to artificially lower $O_2$ saturations, because the pulse oximeter interprets any pulsatile measurement as arterial. [66] Placing the probe on a site above the heart may improve accuracy. Some pulse oximeters have the capability to synchronize pulsations at the probe site to electrocardiographic (ECG) signals, thus enhancing the signal-to-noise ratio.

**Anemia**

Because pulse oximeter measurements depend on light absorption by hemoglobin, they become less accurate and reliable in conditions of severe anemia. However, accuracy is not diminished until the hemoglobin content is <5 mg/dL. [67] [68]

**Ambient Light**

As the pulse oximeter's photodetector is nonspecific, high-intensity ambient light can

produce interference. Surgical, fluorescent, and heating lamps are the common sources of this interference. This problem can be corrected by wrapping the probe with a light barrier, such as a dark cloth or other opaque material. [59]

### Motion

Motion of the probe can produce considerable artifact and inaccurate pulse oximetry readings. However, this phenomenon is transient and seldom influences assessment. Correlating

a pulse oximeter signal with an ECG waveform [64] or using alternate probe sites, such as the ear or toe, also may reduce motion artifact.

### Probe Site

The finger is the most common probe site used for adult pulse oximetry. If the finger is inaccessible or unsuitable, other probe sites, such as the earlobe, nose, and forehead (using reflectance instead of transmittance), may be used. It should be noted, however, that the forehead and nasal bridge probes may be less accurate than the finger and ear probes. [64] In infants and small children, an adhesive sensor unit is preferred. Common sites of attachment include the great toe, the heel, and the lateral aspect of the foot.

### Electrocautery

Electrical interference from devices such as electrocautery also can impair the accuracy of pulse oximetry. This interference can be reduced by increasing the distance between the surgical site and the probe.

## Conclusions

Pulse oximetry is a widely available and relatively inexpensive technology that provides an easy, noninvasive, and generally reliable method to monitor oxygenation. As measurements are continuous, pulse oximetry allows for earlier detection of clinically unsuspected hypoxic episodes than does intermittent arterial blood gas analysis. Frequent measurements should lead to earlier corrective measures with the prevention of adverse consequences.

# CARBON DIOXIDE MONITORING

Capnometry is a noninvasive method used to assess the adequacy of ventilation by measuring the $CO_2$ concentration of exhaled air. With an intact pulmonary circulation, $CO_2$ is present in tracheal but not esophageal gas efflux. The absence of $CO_2$ in an endotracheal tube indicates esophageal intubation, technical malfunction, circulatory arrest, circuit disconnection, or intraluminal/extraluminal tube obstruction. The continued presence of $CO_2$ in the expired air confirms tracheal intubation. In addition, capnometry provides a measure of systemic metabolism and circulation which may be continuously

monitored. Although the measurement of $Pa_{CO_2}$ via arterial sampling is the most direct method of evaluating ventilation, it is invasive, costly, and provides only intermittent data.

Capnography, introduced into clinical practice by Smalhout and Kalenda in the mid-1970s, [69] displays the $CO_2$ measured by capnometry graphically with respect to time throughout the respiratory cycle. The capnogram is the displayed waveform of breath-to-breath variations in the expired $CO_2$ concentration, and characteristic variations in its shape are associated with specific abnormalities. [70]

## Indications

### Verification of Endotracheal Tube Placement

In an emergency situation, the clinician desires a quick and reliable method to verify correct placement of an endotracheal tube (ETT). Traditional clinical methods of evaluating ETT placement (breath sounds, chest movement, epigastric auscultation), although adequate in the majority of circumstances, are not fail-safe. [71] Although, direct cord visualization reliably assesses ETT passage into the trachea, such visualization is not always possible. Additionally, an ETT may become dislodged even after correct placement as a result of head movement or patient positioning. Numerous studies in animals and humans under controlled and emergency conditions support the use of $CO_2$ measurement in expired air as a means of ETT placement confirmation. [54] [71] [72] [73]

### Systemic ("Conscious") Sedation

Many procedures performed in the emergency department are facilitated by sedation. The use of hypnotic doses of benzodiazepines can result in respiratory depression, and opioid analgesics predictably reduce ventilatory drive and the normal response to both hypoxia and hypercarbia. Moreover, the combination of benzodiazepines and opioids substantially increases the incidence of hypoxemia and apnea as compared with the effects of either agent alone. [74]

Monitoring of ventilation, perfusion, and oxygenation increases the safety of sedation. As mentioned earlier, pulse oximetry indirectly assesses ventilation. Although hypoventilation, hypercarbia, and apnea ultimately lead to a decrease in $O_2$ saturation on pulse oximetry, hypoxia is preceded by a rise in end-tidal $CO_2$ partial pressure ($Pet_{CO_2}$). [75] [76] Hence, combining exhaled $CO_2$ monitoring with pulse oximetry should further enhance the safety of systemic sedation.

Recently, nasal cannula (side-stream) $CO_2$ analyzers have made continuous $Pet_{CO_2}$ monitoring possible during systemic sedation. Nasal cannula-derived $Pet_{CO_2}$ values correlate well with $Pa_{CO_2}$ in awake, spontaneously breathing patients and may be as accurate as those obtained from an ETT. [76] Two beneficial features of the $Pet_{CO_2}$ monitor are immediate evidence of changes in the respiratory pattern by observation of the capnographic waveform and an audible apnea alarm. This latter feature is especially valuable after completion of emergency procedures when personnel are less likely to be

at the bedside and patient stimulation is minimized.

**Cardiopulmonary Resuscitation**

The role of $Pet_{CO_2}$ for monitoring the effectiveness of cardiac compressions, estimating the potential for cardiac resuscitation, and detecting restoration of spontaneous circulation is discussed in more detail in Chapter 16 .

**Mechanical Ventilation**

Many EDs manage ventilated patients past the initial resuscitation phase while they are awaiting transfer to a critical care unit or during further diagnostic testing. Capnography can noninvasively and continuously monitor for ventilation failure (e.g., discontinuities in the ventilator circuit, $CO_2$ rebreathing) and assess changes in mechanical support, including weaning from the ventilator. [77]

## Contraindications

In the critically ill patient, capnography may not be an adequate substitute for arterial blood gas sampling during adjustments of or weaning from mechanical ventilation. In such patients, $Pet_{CO_2}$ , when used, should be correlated with $Pa_{CO_2}$ measurements via arterial blood gas analysis. That is,

$Pet_{CO_2}$ values should be used as a supplement to, rather than as a replacement for, $Pa_{CO_2}$ values.

In spontaneously breathing patients, side-stream analyzers with nasal cannula sampling techniques must be used with caution, because ambient air may be entrained, which dilutes $Pet_{CO_2}$ measurements. Moreover, the accuracy of monitoring $Pet_{CO_2}$ by this method is critically dependent on the relative placement of the sampling tube in the patient's naris or nasopharyngeal airway relative to the source of supplemental $O_2$ . The presence of mouth breathing also can dilute $Pet_{CO_2}$ values when nasal cannulas are used.

In children with fast ventilatory rates and low tidal volumes, a side-stream analyzer with a slow sampling flow rate underestimates the $Pet_{CO_2}$ . Sampling flow rates of 150 mL/min yield consistently accurate estimates of $Pa_{CO_2}$ and an acceptable capnogram in neonates, infants, and children. [78] Adult-size disposable end-tidal $CO_2$ detectors are not recommended in children who weigh less than 15 kg, because their small tidal volumes may be diluted in the large (38 mL) dead space of the device, resulting in failure to detect $CO_2$ appropriately. [72] [79]

## Equipment

Of the two quantitative methods of $CO_2$ gas analysis used in hospitals, mass spectrometry and infrared absorption spectrophotometry, only the latter is used

commonly in the intensive care unit and ED. Qualitative $CO_2$ sensitive colorimetric technology also is available. A product comparison of the many commercial capnography devices has been published elsewhere. [80]

The two types of infrared capnometers are as follows:

1. Mainstream (in-line) capnometers, which consist of a transducer that is housed in an airway connector and placed in-line with the patient's breathing circuit (Fig. 6-9) (Figure Not Available) . The transducer contains the infrared light source and photodetector, heated to approximately 40 °C to prevent condensation. Mainstream sampling allows the capnometer to directly assess the patient's respiratory circuit. Hence, gas analysis is nearly instantaneous (<500 msec). The major disadvantage is the weight associated with the airway connector attached to the proximal end of the ETT. Examples of these devices are the Nellcor Stat-CAP N60B and Ultra-CAP N6000B (Nellcor Inc., Pleasanton, Calif). The former device is a portable, battery-operated instrument that provides continuous qualitative readings. The latter device is a bedside monitor that displays both a continuous waveform and numeric information.
2. Side-stream, or diverting capnometers, actively withdraw gas from the patient's airway via a sampling tube, and the concentration of $CO_2$ is measured in the machine rather than in the ETT (Fig. 6-10) (Figure Not Available) . The major advantage of side-stream analyzers is their applicability to non-intubated patients. Their major disadvantage is a slower response time, because expired gas must be transported to the capnometer itself for analysis. Slower response time results in dispersal of the gas bolus due to convection and diffusion during transit through the sampling catheter. These factors result in an underestimation of $Pet_{CO_2}$ , particularly in children who have high ventilatory rates and small tidal volumes. Response times of side-stream analyzers are dependent on the aspiration flow rate, sampling tube length, and tubing diameter. To achieve predictable $Pet_{CO_2}$ values and $CO_2$ waveforms, the response time of the analyzer must be less than the respiratory cycle of the patient. [81] The optimal gas sampling flow rate is considered to be 50 to 200 mL/min, which ensures that the capnographs are reliable in both children and adults. [82] Despite a water trap, side-stream analyzers also are affected by secretions, saliva, and water condensation.

Qualitative, lightweight, disposable end-tidal $CO_2$ detection devices are based on colorimetric changes. A pH-sensitive chemical indicator is enclosed in a plastic housing and is connected to the gas stream between the ETT and the ventilator. The concentration of $CO_2$ in ambient air or the esophagus is <0.3%. These devices change color when the concentration of $CO_2$ is higher than 4% or 5.4%. The color varies as the $CO_2$ level increases and decreases between expiration and inspiration. The devices are designed to function for approximately 2 hours. The response time of the device is sufficiently fast to detect changes of $CO_2$ breath by breath. [83] In addition to their portability and single-patient use, these devices have the advantage of not requiring electrical power. Originally, the disposable $CO_2$ detectors were only available for attachment to ETTs (EASY-CAP and Pedi-CAP, Nellcor Inc., Pleasanton, Calif). Recently, chemical $CO_2$ detection devices, built into disposable bag-valve ventilation devices, are available for emergency department use (CAPNO-FLO, Kirk Specialty

Systems, Carrollton, Tex). Both systems have components for adult and pediatric patients.

## Procedure

For mainstream capnometers, simply place the airway connector in-line between the ETT and respiratory circuit. For side-stream or diverting capnometers, position the sampling tube in the naris via nasal cannula, nasopharyngeal tube, or other adapters available with particular machines. After sufficient warm-up time, a continuous recording of the capnogram or a digital display of a $Pet_{CO_2}$ value will be displayed depending on the type of machine used. The chemical $CO_2$ detection devices are ready to use after attachment to the ETT (EASY-CAP, Pedi-CAP), or they come as a component of the bag-valve device (CAPNO-FLO).

## Interpretation

Various factors result in either increased or decreased (or even absent) $Pet_{CO_2}$ (Table 6-5) . With regards to the measurement device, a continuous recording of the capnogram is more advantageous than simply a digital display of a $Pet_{CO_2}$ value.

A normal capnogram has four phases (Fig. 6-11) (Figure Not Available) . At the onset of exhalation (point B) respiratory gases are free of $CO_2$ , because they represent the anatomic dead space. The steep rising slope of segment B-C represents the emptying of rapidly exchanging alveoli. Segment C-D represents the emptying of uniformly ventilated alveoli, where the concentration of exhaled $CO_2$ is nearly constant. True end-tidal $CO_2$ ($Pet_{CO_2}$ ) is the highest concentration measured during the alveolar plateau (point D) and immediately precedes the onset of the next inspiratory cycle. Inspiration is represented by the rapidly descending limb of the capnogram (segment D-E) and, unless significant $CO_2$ rebreathing occurs, return of the $CO_2$ concentration to near zero (baseline).

At the end of exhalation, the composition of expired air closely reflects that of alveolar air. Under normal conditions, the alveolar $CO_2$ reflects the $CO_2$ present in mixed venous blood ($Pv_{CO_2}$ ), which equilibrates with the resultant value for arterial blood ($Pa_{CO_2}$ ). Under normal conditions, only a small gradient (<6 mm Hg) exists between $Pa_{CO_2}$ and $Pet_{CO_2}$ . [84] The $P(a-et)_{CO_2}$ gradient is increased with age, COPD, pulmonary embolism, decreasing cardiac output, hypovolemia, and anesthesia itself. [85] [86] [87]

The principal determinant of the size of the $Pa_{CO_2}$ -$Pet_{CO_2}$ gradient ($P[a-et]_{CO_2}$ ) is the matching of ventilation and perfusion (V/Q). The major cause of V/Q mismatch is dead space ventilation, in which lung units have more ventilation than perfusion. As a result, the end-tidal gas contains less $CO_2$ , and $Pet_{CO_2}$ values are lower, causing large differences in the $Pa_{CO_2}$ -$Pet_{CO_2}$ gradient. [87] [88] [89] In this situation, the alveolar plateau (see Fig. 6-11 (Figure Not Available) , segment C-D) will not be flat, but rather will have a slow, rising expiratory upstroke (Fig. 6-12) (Figure Not Available) . In a normal patient, the alveolar plateau is flat because the expired gas from all lung units have similar V/Q relationships. [86] If the patient has significant maldistribution of ventilation, exhaled gas will have varying concentrations of $CO_2$ , because the $CO_2$ concentration from some

airways will be low, representing dead space ventilation, whereas the $CO_2$ concentration from others will be high. Only when a distinct alveolar plateau is present can it be assumed that true alveolar gas is being sampled and analyzed. [77]

**Intubation Assessment**

False-positive capnographic tracings associated with esophageal intubation that closely mimic successful ETT intubation may occur in patients who have recently ingested carbonated beverages or antacids and those receiving mask ventilation with resultant gastric insufflation of $CO_2$ -containing gases. [90] However, after 3 to 6 esophageal ventilations, $Pet_{CO_2}$ concentration rapidly declines as gastric $CO_2$ is washed out and

| TABLE 6-5 -- Various Factors That Influence $Pet_{CO_2}$ | | | | |
|---|---|---|---|---|
| **Effect on Pet $_{CO_2}$** | **Factor** | | | |
| | **$CO_2$ production** | **Pulmonary perfusion** | **Alveolar ventilation** | **Technical/mechanical errors** |
| Increased | Fever | High cardiac output | Hypoventilation | Exhausted $CO_2$ absorber |
| | Thyrotoxicosis | Hypertension | Bronchial intubation | Inadequate fresh gas flow |
| | Malignant hyperthermia | | Partial airway obstruction | Leaks in breathing system |
| | Sodium bicarbonate | | Rebreathing | Faulty ventilator |
| | | | | Faulty valves |

| Decreased or absent | Hypothermia | Low cardiac output | Hyperventilation | Circuit disconnection |
|---|---|---|---|---|
| | | Hypotension | Apnea | Sampling tube leak |
| | | Hypovolemia | Total airway obstruction | Malfunction of ventilator |
| | | Pulmonary embolism | Partial airway obstruction | |
| | | Cardiac arrest | Tracheal extubation | |

diluted with fresh gas (Fig. 6-13) (Figure Not Available) . [73][91]Tracheal ventilation will of course continue to produce a normal waveform.

After initial successful ETT placement and confirmation, changes in the $CO_2$ waveform can provide immediate detection of tube-related adverse events. When the ETT is partially obstructed, the capnogram will have a slow upstroke without a significant change in the $Pet_{CO_2}$ (Fig. 6-14) (Figure Not Available) . [73] [77] Bronchospasm and COPD exacerbations produce obstruction to expiratory gas flow, thus increasing the slope of the expiratory upstroke. With inadvertent extubation, the capnogram shows a sudden drop in $Pet_{CO_2}$ (the same change that occurs when the tube becomes completely obstructed or malpositioned in the esophagus) (Figs. 6-15 (Figure Not Available) and 6-16) (Figure Not Available) . [73] ETT cuff leaks yield low $Pet_{CO_2}$ values because of the partial escape of the expired gas around the tube.

**Monitoring Ventilation**

Capnography is useful in diagnosing and monitoring maldistribution of ventilation during mechanical ventilation. In patients with a large V/Q mismatch, the capnogram will have a continued rise throughout the expiratory phase (see Fig. 6-12) (Figure Not Available) and will lose the normal alveolar plateau. When this waveform occurs, the measured end-tidal $CO_2$ may not represent a good estimate of $Pa_{CO_2}$ . However, by monitoring the slope of the expiratory phase on the capnogram, the efficacy of therapy can be evaluated. For example, in the case of asthma, as bronchospasm resolves, the slope of the expiratory phase will become less steep and the alveolar plateau better defined as a

result of improved distribution of ventilation. [77]

Furthermore, as the P(a-et)$_{CO_2}$ gradient is sensitive to increases in dead space, this gradient can be used to evaluate changes and trends in dead space ventilation in critically ill patients with significant intrapulmonary shunting. [92] [93] It also can be used as a guide to determine the best positive end-expiratory pressure (PEEP) level for optimal oxygenation. Because a low P(a-et)$_{CO_2}$ gradient implies the optimal V/Q relationship, the level of PEEP that produces the lowest P(a-et)$_{CO_2}$ gradient is the level at which optimal alveolar recruitment occurs. [94]

Excluding ventilator setting changes and circuit discontinuities, a sudden drop in end-tidal $CO_2$ may be an early indicator of shock or pulmonary embolism. [69] [95]

A dip in the plateau (curare cleft) (Fig. 6-17) (Figure Not Available) indicates a spontaneous respiratory effort during mechanical ventilation [96] [97] and may serve as an early clue to the waning of the effects of a paralytic agent. Capnometry may also be especially useful in assessing the adequacy of hyperventilation in the hemodynamically stable patient with head trauma. Other capnography patterns and their clinical significance are demonstrated in Figure 6-18 (Figure Not Available) .

## OXYGEN THERAPY

Earlier sections have dealt with ventilation and assessment of oxygenation. Delivery of $O_2$ is impaired in many clinical situations. Neurologic dysfunction is an early sign of hypoxemia. Otherwise-healthy individuals begin to experience short-term memory loss, euphoria, and impaired judgment when the Pa$_{O_2}$ level approaches 55 mm Hg. Progressive loss of cognitive and motor function, increasing tachycardia, and other physical signs occur when values are between 30 and 55 mm Hg. When levels are <30 mm Hg, the patient loses consciousness. Pa$_{O_2}$ is a function of the fraction of inspired $O_2$ tension (Fi$_{O_2}$ ), the alveolar ventilation, and the relative distribution of both ventilation and perfusion in the lung. Supplemental $O_2$ can increase the amount of $O_2$ dissolved in blood enough to deliver one third of the body's resting metabolic requirements. This section reviews the noninvasive delivery of supplemental $O_2$ .

### Indications

Oxygen therapy is generally indicated when hypoxia is present (Pa$_{O_2}$ <60 mm Hg or Sa$_{O_2}$ <90 to 95%). Clinical situationsthat are commonly associated with hypoxia and generally benefit from supplemental $O_2$ include pulmonary disease, cerebrovascular accidents, gastrointestinal bleeding, shock, and trauma. Supplemental $O_2$ also is indicated when hypoxia is anticipated from a procedure such as intubation or before a procedure in which intravenous analgesia may cause respiratory depression.

High altitude also results in hypoxia. At 7000 ft the barometric pressure is 564 mm Hg, the atmospheric partial pressure of $O_2$ is 116 torr, and the arterial partial pressure of $O_2$

(with healthy lungs) is approximately 63 torr. Commercial airlines maintain cabin pressures at levels between 5000 to 8000 ft at most cruising altitudes, and close to 10,000 ft temporarily under certain circumstances. Patients with chronic hypoxia may require supplemental $O_2$ , and they must contact the airline before flying to make appropriate arrangements (the reader is referred elsewhere for a review of air travel and $O_2$ therapy). [98] Oxygen is specifically indicated for carboxyhemoglobinemia; 100% $O_2$ reduces the half-life of carboxyhemoglobin from a mean of 5 hours to 1 hour; hyperbaric (more than 1.0 atm) $O_2$ can lessen this time by half again. However, discussion of hyperbaric $O_2$ therapy is beyond the scope of this chapter.

**Contraindications**

Paraquat turns $O_2$ into free radicals, thus making $O_2$ a substrate of the poison. Similar toxins in this group include bleomycin, cyclophosphamide, doxorubicin, ozone, and nitrous dioxide. [99] [100] Hence, $O_2$ therapy in the absence of documented hypoxia is contraindicated for this group of toxins.

Fears of ventilatory shutdown in the presence of $CO_2$ retention have made physicians hesitant to give supplemental $O_2$ in amounts greater than 2 L/min. However, if hypoxia remains after low-flow $O_2$ is initiated, the $O_2$ delivery must be increased. Continuous monitoring of spontaneous respiration is required in this setting, and preparations to perform intubation should be made to assist the patient's ventilation if indicated. Note that inspired $O_2$ levels may actually rise with low-flow $O_2$ therapy as respiratory effort wanes, because less room air is entrained with shallow breaths; significant exacerbation of ventilatory failure has been documented with even 1 L/min of $O_2$ by nasal cannula. [101] However, a high $CO_2$ level is not a contraindication to appropriate $O_2$ therapy.

**Equipment**

The two most common sources of $O_2$ for the patient in the hospital are wall outlets linked to a large reservoir of liquid $O_2$ and $O_2$ tanks (green by convention) of various sizes, listed in Table 6-6 . Both provide outlet pressures in the range of 30 to 50 psi. An approximation of the amount of time left in a given tank at a given flow rate may be calculated using the following formula:

Minutes of $O_2$ = gauge pressure (psi) × cylinder factor/flow rate (L/min)

Cylinder factors are shown in Table 6-6 . Alternatively, a simple computer program is available that can estimate the duration of $O_2$ remaining in a tank based on the previous

**TABLE 6-6** -- Oxygen Cylinders (Approximate Values)

| Cylinder Type | Volume (L) | Cylinder Factor | Hours of $O_2$ at 2 L/min |
|---|---|---|---|
| D | 450 | 0.20 | 3.5 |
| E | 650 | 0.28 | 5.0 |
| G | 5600 | 2.41 | 44.0 |
| H, K | 6900 | 3.14 | 58.0 |

variables. [102] The numerous methods available to deliver $O_2$ from the source to the patient are listed in Table 6-7 .

Nasal cannulas are capable of providing low-flow $O_2$ supplementation when accurate control of $O_2$ concentration is unimportant, as inspired concentrations vary considerably depending on patient tidal volume and inspiratory flow rate. [103] Rough guidelines for inspired $O_2$ concentration related to $O_2$ flow rates are listed in Table 6-7 . Similarly, some mask systems are designed to be used without Venturi inserts, and package inserts indicate the range of inspired $O_2$ concentration based on $O_2$ flow rates. As with nasal cannulas, inspired $O_2$ concentrations vary considerably (may be upward of 10% greater than predicted by package inserts) depending on the patient's breathing pattern (rate and tidal volume).

Venturi systems should be used in patients with $CO_2$ retention for whom tight control of inspired oxygen is required. A partial non-rebreathing mask incorporates a 200 mL reservoir that effectively delivers an inspired $Fi_{O_2}$ of 60

**TABLE 6-7** -- Oxygen Delivery Systems

| System | Flow Rate L/min | FIo$_2$ (% Oxygen) | Advantages | Disadvantages |
|---|---|---|---|---|
| Nasal cannulas | 1<br>2<br>3<br>4<br>5<br>6 | 25<br>29<br>33<br>37<br>41<br>45 | Simple, comfortable, inexpensive, allow eating and drinking | Can cause local irritation and drying of mucous membranes (primarily for flow rates >4 L/min) |
| Simple oxygen masks | >5 L/min | 35-50 | Deliver higher flow rates than nasal prongs | Must be removed for airway care, eating, and drinking |
| Masks with reservoir bag | Up to 15 L/min | 60 | Higher FIo$_2$ at lower flow rates | Risk of atelectasis and oxygen toxicity (with prolonged use) |
| Venturi masks | 4<br>6<br>8<br>10 | 24-28<br>31<br>35-40<br>50 | More precise control of final oxygen concentration | Same as above |
| Reservoir nebulizers, includes CPAP, T-tubes | 40 L/min plus: | 60-90 | Can deliver increased humidity, positive pressure | Risk of barotrauma |

to 80% in most patients. The system uses a 200 mL reservoir bag, initially filled with $O_2$. Inspiration at high flow rates generally empties the reservoir and exhalation fills it with the first 200 mL of expired gas, which is mostly derived from the dead space of the upper airway and thus contains a high FiO2. A true non-rebreathing mask contains two types of valves and is capable of delivering close to 100% $O_2$. One valve prevents exhalation gas from entering the reservoir bag. The second type (actually two valves),

are located on the mask and allow exhalation, concurrently preventing ambient air from entering the inhalation circuit. To comply with safety regulations designed to prevent asphyxiation should the $O_2$ supply be interrupted, many manufacturers remove one of the valves located on the mask, somewhat limiting the concentration of $O_2$ delivered.

## Procedure

Supplemental $O_2$ should be given to increase the $Pa_{O2}$ to between 60 and 80 mm Hg or between 90 and 95% $Sa_{O2}$. In attempting to deliver high concentrations of $O_2$ to a non-intubated patient, the challenge is to provide enough $O_2$ at flow rates sufficient to meet the patient's demands. A simple method of assessing the adequacy of $O_2$ delivery with a medium flow system is to add water mist to the $O_2$ (through a humidifier) and to visually observe the pattern of mist flow at the mask. Mist should escape from the side holes of the mask during both inspiration and expiration. If mist is not visualized to escape during inspiration, ambient air is being inspired by the patient (effectively reducing inspired $O_2$ concentration) and a higher flow system is required. Bedside pulse oximetry can provide prompt monitoring of changes in $Sa_{O2}$, allowing adjustments to be made without repeated arterial blood gas determination. Pulse oximetry values generally equilibrate within 5 minutes of an oxygen delivery adjustment. [104]

Evidence of $CO_2$ retention, such as decreasing mental status and failing respiratory drive, indicates the need for an arterial blood gas determination to document the $Pa_{CO2}$; however, the decision to intubate generally should be made on clinical grounds. The need to humidify bedside low-flow $O_2$ is unproven. [100] [105] Providing $O_2$ from cylinders involves several steps that are outlined in Table 6-8 .

## Complications

Three distinct areas of risk accompany supplemental $O_2$ use: (1) respiratory dysfunction, (2) cytotoxic injury, and (3) physical hazards. Respiratory dysfunction results from $CO_2$ retention and atelectasis. Variations in $CO_2$ level provide the main stimulus to breathe in normal subjects. Patients with COPD have a decreased sensitivity to $CO_2$ levels secondary to chronic exposure to higher $CO_2$ levels, and hypoxia provides backup support for the respiratory drive. Oxygen given in sufficient amounts can remove the remaining chemical stimulus to respiration and has the potential to cause respiratory shutdown.

| TABLE 6-8 -- Operation of Oxygen Cylinders |
| --- |
| 1. Secure the tank in an upright position so that it will not move or fall while being manipulated. |

| |
|---|
| 2. Remove the cylinder seal ("E" tank) or cylinder cap ("G," "H" tank). |
| 3. Turn the cylinder valve on and off quickly to clear ("crack") the valve. On the "E" tank, this is done with a wrench; on the "G" or "H" tank, it is done with the cylinder handle. |
| 4. Check the yoke to ensure that it is compatible for use with oxygen, and place it on the cylinder, being sure that the fittings are compatible. |
| 5. Tighten the yoke, making certain that any necessary gasket is in place. |
| 6. Close the needle valve. |
| 7. Slowly open the cylinder valve until the pressure maximizes. |
| 8. Observe that the cylinder contains an adequate supply of gas. |
| 9. Connect the desired secondary delivery system (e.g., nasal cannula). |
| 10. Open the needle valve so that the desired oxygen flow registers on the flow meters. |

The complete abolition of the hypoxic drive has been reported to require a $Pa_{O_2}$ of 200 mm Hg. However, administration of 100% $O_2$ to 22 patients with COPD in acute respiratory distress (mean baseline blood gas values: $Pa_{CO_2}$ = 65 mm Hg, $Pa_{O_2}$ = 38 mm Hg) for 15 minutes resulted in only a transient decrease in minute ventilation. [106] The lowest values for minute ventilation were reached between 20 and 180 seconds from onset of inhalation, followed by a slow rise over the next 12 minutes to within 93% of the control value. The decrease was the result of falls in both tidal volume and

respiratory rate; however, after 15 minutes, these parameters had returned to baseline levels. Despite little difference in these parameters at the 15 minute point, $Pa_{CO_2}$ had risen a mean of 23 mm Hg, and $Pa_{O_2}$ had risen a mean of 225 mm Hg. [107] The mechanism leading to atelectasis is less clear. Elevated $O_2$ levels may affect underperfused or underventilated pulmonary segments by decreasing hypoxic vasoconstriction. The increased perfusion could lead to greater absorption of the remaining gas, destabilizing the alveolar units and bringing on collapse. [108]

Cytotoxic damage, theoretically secondary to free radical production, leads to tracheobronchitis and adult respiratory distress syndrome (ARDS) manifested by pulmonary edema and focal lung collapse with pulmonary fibrosis as a long-term consequence. The mechanism of damage has been shown experimentally to include oxidation of carbohydrates with disruption of cell surface receptors, DNA-RNA alterations, lipid peroxidation, and protein denaturation. Administration of an inappropriately high level of $O_2$ does not usually produce consequences within the time frame of the emergency department visit. The risk of $O_2$ toxicity depends on several factors, including $O_2$ tolerance (the state of biologic resistance to $O_2$ -induced damage, which is itself dependent on antioxidant defenses, age, and nutritional and hormonal factors), concentration of $O_2$ delivered, and duration of treatment. The goal is to deliver the least $O_2$ required to achieve adequate tissue levels. During resuscitation and most emergency care, 100% $O_2$ can be delivered safely to most patients without fear of cytotoxic injury. Healthy adult volunteers have received 100% $O_2$ for up to 6 hours without evidence of pulmonary injury. Except in special circumstances, such as paraquat poisoning, $O_2$ at concentrations of 50% is safe for 2 to 7 days. [100]

Physical risks associated with $O_2$ therapy include trauma associated with tank explosions, fire hazard, local irritation, and drying of mucous membranes.

## NONINVASIVE PRESSURE SUPPORT VENTILATION

Noninvasive pressure support ventilation can be used to deliver increased airway pressure in several modes: (1) pressure increases solely during inspiration (i.e., delivery of inspiratory positive airway pressure [IPAP]) to supplement ventilatory mechanics; (2) continuous steady positive airway pressure maintained throughout the ventilation cycle (i.e., expiratory positive airway pressure [EPAP], also known as continuous positive airway pressure [CPAP]) to improve alveolar oxygen exchange; or (3) a combination of both modalities to achieve both goals. During noninvasive pressure support ventilation, a tight, well-fitting mask is placed over the patient's mouth and nose or just over the nose.

Mask CPAP treatment of cardiogenic pulmonary edema was first described more than 50 years ago [109] and has been shown to be a useful adjunct in the treatment of acute cardiogenic pulmonary edema. Mask CPAP results in early physiologic improvement and reduces the need for intubation and mechanical ventilation in patients with pulmonary edema. [110] [111] [112] It also reduces total hospital costs for patients with severe cardiogenic pulmonary edema. [113] Use of mask CPAP to deliver PEEP has

aided the treatment of other forms of respiratory failure including those due to pulmonary infections, trauma, and obstructive lung disease. Patients with respiratory failure secondary to *Pneumocystis carinii* pneumonia who require mechanical ventilation have in-hospital mortality rates as high as 86 to 94%; however, those who were judged to require mechanical ventilation, but who were instead treated with mask CPAP, have in-hospital mortality rates of 22 to 55%. [114] [115] [116] Mask CPAP may be efficacious in the treatment of respiratory failure secondary to other pulmonary infections. [117] [118] Further, mask CPAP (either by full-face or nasal mask) may obviate the need for intubation and mechanical ventilation in acute exacerbations of COPD. [119] [120] [121]

The general use of IPAP for respiratory failure has recently been reviewed. [122] The use of combined IPAP and EPAP in the ED and critical care setting appears promising. [123] [124] [125] [126] This technique is also known as bi-level positive pressure ventilation, because it allows the clinician to deliver different inspiratory and expiratory pressures. This technology offers the opportunity to both support mechanical ventilation and to improve oxygen exchange through an enhanced functional residual capacity. In essence, a mask device provides the ventilation and PEEP that was once possible only with the use of tracheal intubation and a standard ventilator.

**Indications and Contraindications**

Noninvasive pressure support ventilation is indicated for the treatment of impending ventilatory failure in an attempt to avoid intubation and standard mechanical ventilation, with their associated morbidity and mortality. Noninvasive pressure support ventilation seems best applied to patients whose respiratory failure is expected to quickly respond to medical therapy, as continuous long-term mask CPAP or ventilation requires close attention.

Noninvasive pressure support ventilation for acute respiratory failure requires an alert patient capable of protecting the airway and handling secretions. Other contraindications include an inability to obtain a good mask fit, cutaneous irritation from the mask, and inability to cooperate with the therapy. Finally, intubation and standard ventilation is preferred for patients who require total ventilatory support, because the mask may slip and effective ventilation may cease.

**Equipment**

Although a number of systems that provide CPAP are on the market, this technique is infrequently used in the ED. A small, noninvasive bi-level positive pressure ventilation system (BiPAP System, Respironics Inc., Murrysville, Pa) that permits use of a nasal (rather than facial) mask alone *in lieu* of tracheal intubation may be most useful in the emergency department. [126] Therefore, an overview of the use of the BiPAP System is given below. The advantage of the BiPAP System is that it supplies air or $O_2$ at a pressure and flow rate that are suitable for assisted *inhalation and expiration* by sensing the patient's spontaneous breathing efforts and automatically adjusting to compensate for variations in ventilatory requirements, even in the presence of airway leaks. *Importantly, this device is not intended to be a life support ventilator, because it is used only to temporarily augment spontaneous breathing.* Regardless of the system used,

close attention to manufacturer guidelines is advised.

**Procedure**

Prior to initiation of this technique, the patient must be informed of the purpose of the nasal mask and cooperation ensured. It helps to inform the patient of the alternative therapy should this technique not meet the patient's needs. It also helps to reassure the patient that the operator will stay with the patient until he or she is comfortable with the mask and ventilator system. Baseline vital sign and oxygenation measurements are made.

*The patient should be treated in a closely monitored setting where his or her vital signs and respiratory status are closely monitored.* Despite intervention with this system, emergent intubation and mechanical ventilation may become needed. Equipment for airway support (e.g., $O_2$ source, tubing, bag-valve mask, laryngoscope, suction equipment, and various airways) should be immediately available.

The BiPAP System components are assembled and connected to oxygen--generally at the same flow settings as the patient is currently receiving (generally at 10 to 15 L/min). The pressure tubing is attached to the airway pressure monitor and the pressure monitor is turned on; the main system is then turned on and a ventilation mode is selected. Generally, the system will be used in the spontaneous ventilation mode (i.e., to support spontaneous ventilations) with an initial EPAP setting of 3 to 5 cm $H_2O$ and an IPAP setting of 8 to 10 cm $H_2O$.

Ideally, a mask sizing gauge (Fig. 6-19) (Figure Not Available) is used to choose a mask size that does not place direct pressure on the bridge of the nose, the lateral *ala nasi*, the inferior nasal septum, or the lip. The mask may be initially held in place by the operator as the patient adjusts to the ventilatory support. With the mask in place, the BiPAP System settings are modified to optimize patient ventilatory status (Fig. 6-20) (Figure Not Available) . As the patient becomes more comfortable, the mask is secured in place on the face using self-adhesive binding straps (Fig. 6-21) (Figure Not Available) . If time permits, the headgear straps may be loosely attached prior to placement and the mask slipped over the head as a unit; the straps are then tightened.

The patient is encouraged to breathe with the mouth closed. The facial mask fit should be adjusted for comfort and to minimize air leak, especially about the eyes. When the patient has accepted the mask and the clinical status has stabilized, the patient may be permitted to speak and even to eat small amounts.

Adjustments in the EPAP and IPAP settings are generally made in 2 cm $H_2O$ increments. Near optimal settings can generally be attained within 10 minutes. Periodic blood gas measurements should be coupled with ongoing vital sign and pulse oximetry measurements. When available, a $CO_2$ device side-flow catheter can be placed under the nasal mask for monitoring exhaled $CO_2$ levels. Increases in IPAP settings generally increase tidal volume and decrease $CO_2$ levels, whereas increases in EPAP generally increase functional residual capacity and increase $O_2$ levels. The concentration of inspired oxygen also can be modified by changing the $O_2$ flow rate. High levels of EPAP

or IPAP can induce PEEP-related reductions in cardiac preload. Further, although the system can adjust for some air leak about the mask, higher pressures require a tighter mask fit and can increase patient discomfort.

If the patient's hypoxic drive is diminished, decreased spontaneous ventilatory effort may be noted. If this situation occurs, the BiPAP System should be changed to the "spontaneous/timed" mode, which permits spontaneous breaths but imposes a mandatory ventilation if an extended ventilatory pause is noted. When initiating this mode, the clinician generally sets the respiratory rate at 10 breaths/min. At this setting, when a breath does not occur within 6 seconds of the preceding breath, a mandatory breath is provided.

If the patient requires a brief period of hyperventilation to help coordinate ventilatory efforts, the BiPAP System can be set to the "timed" mode and a respiratory rate of 15 to 20 breaths/min can be initiated. In this mode, the %IPAP time must be set by the operator. A %IPAP of 30% produces an inspiratory-to-expiratory (I:E) ratio of 1:2.3, whereas a %IPAP of 40% produces an I:E ratio of 1:1.5.

Aerosolized medications can be delivered either through in-line "T-pieces" in the BiPAP System circuit or through standard mouthpiece units (see following section).

**Complications**

Complications of these forms of therapy include facial irritation, abrasion, or even facial necrosis; conjunctivitis due to mask air leak; aspiration; and gastric distention. A wound care dressing on the bridge of the nose may reduce skin abrasion. [125] Nasogastric tubes have been used to relieve gastric distention, although a nasal mask system is less likely to produce gastric distention. Additionally, although the pressures used are generally low, all of the complications of positive pressure ventilation may be seen with this technique.

**Conclusions**

Positive pressure ventilation modalities offer the promise of averting the need for intubation and mechanical ventilation in certain groups of patients with acute respiratory failure. The procedure for instituting these therapies is relatively simple and may even have potential in the out-of-hospital setting. Additionally, although best studied in adults, these therapies have been applied to pediatric patients, [127] [128] and pediatric masks are available commercially.

# DELIVERY SYSTEMS FOR INHALED MEDICATIONS

Inhaled substances have been used for medicinal (and social) purposes since the beginnings of recorded history. Among the earliest of such records on the treatment of respiratory disease comes from a monograph written in 2737 B.C. by the Chinese

emperor Shen Nung on the use of inhaled cannabis for the treatment of asthma. [129] Later in the 15th century B.C. the Chinese *Pharmacopeia* refers to cannabis and to *ma huang*, a medicinal that contained ephedrine, as therapy for asthma.

Through the 1900s, atropinic effects were obtained from ingestion and inhalation of medicinals such as *Atropa belladonna* and *Datura stramonium*. Thus, long before the era of modern medicine, beta-adrenergic and antimuscarinic stimulation by inhalation were established in the physician's armamentarium.

When compared with oral or parenteral delivery, the aerosolized delivery of certain medications to patients suffering from bronchospasm has been found to be particularly effective. With fewer side effects and better patient acceptance, aerosolization has become the route of choice in contemporary clinical practice. Aerosolized medications are easily delivered using portable self-contained sprays called metered-dose inhalers (MDIs) and by nebulizer devices propelled by air compressors or wall $O_2$ . Either method can be used in the home, outpatient department, or in-hospital setting. Both modalities also can be delivered in-line with ventilation equipment for intubated patients and by mask for young or weak patients. However, the use of MDIs in intubated patients has not been well defined, and the modality's efficacy remains unproven. [130]

Intermittent positive-pressure breathing (IPPB) as a means of assisting simple nebulizer therapy has received much criticism and is no longer commonly used. Some delivery systems used inhaled dry medication (Ventolin Rotahaler and Bricanyl Turbuhaler). These systems are inspiratory flow driven and eliminate the coordination problems encountered with MDIs. Additionally, the Bricanyl Turbuhaler contains no propellants or lubricants and may reduce the incidence of allergy to the adjuvants commonly found in MDIs. Though they have been used extensively outside the United States, their role in the management of bronchospasm in the acute care setting is uncertain. Hence, these systems are not discussed further in this chapter.

**Indications and Contraindications**

Nebulizers and MDIs deliver medications by the pulmonary route for the treatment of bronchospasm. Metered-dose inhalers also are used to deliver steroids, mucolytics, and ergotamine tartrate for migraine headache. [131] Gentamycin and other antibiotic solutions have been nebulized for antimicrobial therapy. Aerosolized racemic epinephrine is employed to treat croup and aerosolized pentamidine has been developed for the treatment of *Pneumocystis* pneumonia.

Spacer devices permit effective drug delivery with MDIs even in patients with poor hand-inhalation coordination. [132] In the setting of effective pulmonary drug delivery, inhalant therapy is preferred over the intravenous or subcutaneous routes for reasons of convenience, safety, and patient comfort.

Historically, the MDI has been used primarily in the home and nebulizers primarily in the inpatient and outpatient clinical settings; however, this division is becoming less distinct as more patients obtain compressor-driven devices for home nebulizer use and the MDI is restudied for use in the hospital setting. An MDI combined with a spacer increases

efficacy, and recent studies show no detectable difference in effectiveness of albuterol administered by nebulizer or an inhaler system consisting of an MDI combined with a spacer. [133] [134] The same findings have been reproduced in the treatment of children ages 6 to 14 years, [135] and MDIs (combined with spacers) have been successfully used for treating infants (ages 1 to 18 months) with wheezing. [136] Despite these convincing studies, nebulization remains the more widespread technique for beta-agonist delivery in both out-of-hospital and in-hospital settings.

The benefits of replacing nebulizers with MDIs in the hospital setting include decreased costs, quicker treatments, and better patient education in anticipation of later home use. Less nursing and respiratory technician time are required with MDI therapy. [137] Nebulizers have two advantages over the MDI: (1) more than one medication can be given simultaneously; and (2) the system can be used in a hands-off fashion for the young, critically ill, or intubated patient. Spacers are indicated for patients who cannot adequately coordinate activation of the MDI with inhalation, to increase drug delivery, and for the prevention of oral candidiasis in the case of inhaled steroids.

Contraindications to use of these devices are few. The MDI may be difficult for the very young, elderly, or critically ill to use, either because of an inability to cooperate, weakness,or difficulty coordinating breathing with activation of the MDI. Spacer devices make the coordination of MDI use with inspiration less critical and, as noted earlier, have been used in the treatment of young infants. Oxygen-powered nebulization may be contraindicated in the case of $CO_2$ -retaining patients. [138]

## Metered-Dose Inhaler Use

### Equipment and Particle Delivery

Metered-dose inhalers consist of small canisters of highly pressurized liquid with a Freon propellant. An activator valve allows the delivery of consistent doses of medication in an aerosolized form. Particles of 1 to 5 mum in diameter are the most desirable size to achieve efficient peripheral airway deposition. [139] Ideally, the MDI output will have up to 13% of particles in this range, as opposed to only 1 to 5% for the nebulizer. The deposition of aerosol in the lower respiratory tract is a function of inertia and gravitational sedimentation.

Inertia limits the quantity of drug delivered to the therapeutic site because particles in motion, such as the drug suspended in nebulized liquid, have a tendency to move in a straight line, resulting in the majority of the drug bombarding the posterior pharynx. The open-mouth technique (as opposed to lips closed around the inhaler), with the inhaler held a few centimeters from the mouth, has been found to reduce this pharyngeal deposition. [140] By slowing the velocity of the particle, the airflow into the respiratory tract can have proportionately more time to effect transport or "entrain" the drug.

Spacer devices (see the following section) similarly allow for deeper penetration by reducing particle velocity, which in turn reduces droplet size both through the evaporation of the propellant that coats the drug crystal and the sedimentation of the larger particles. More central deposition occurs in patients with severe bronchial asthma

and chronic bronchitis because of the underlying airway obstruction. In this situation, fewer particles remain to be deposited further downstream because of early gravitational sedimentation. Centrally deposited particles are carried by mucociliary transport to the larynx and are swallowed, increasing the systemic absorption. Breath-holding enhances absorption by allowing the deposition of the smaller particles (less than 5 mum) that require up to 2 seconds to settle onto the walls of the terminal bronchioles. [140]

**Procedure**

The most important factor in determining the successful use of the MDI is the patient. Up to 78% of patients use the inhaler incorrectly, [141] and even after careful instruction, 14% still fail to perform efficiently. Furthermore, when housestaff and attending staff were evaluated, half the physicians could not assemble the device correctly, and only 4 of 55 performed all seven steps correctly; 3 of the 4 successes were among asthmatic physicians. [142] Others have confirmed that health care providers lack basic knowledge of inhalation therapy. [143]

Lower temperatures decrease the internal pressure and result in an increase in the size of the particles; therefore, the canister should be kept at room temperature. Lack of use can result in abnormally low doses, up to 50% less than expected. If the device has not been used for several days, it should be activated once or twice before actual use. [131] In the past, patients have been told to activate the inhaler at the beginning of inhalation, immediately after full expiration. Studies of patients with diseased small airways suggest that beginning activation somewhat later in the inspiration period may result in a greater bronchodilator effect by overcoming the requirement for a higher opening pressure, [144] [145] but this finding remains controversial. [146] [147] Spacer devices and inspiration-triggered inhalers exist for the patient who has difficulty coordinating these tasks.

*Before using the MDI*, it is important that the patient or clinician visualize the mouthpiece to ensure the absence of foreign material that might be inhaled with device activation. The aspiration of small coins and other foreign material have occurred when the device has been kept in the patient's pocket or purse. Although the device protective cap should be used during storage and will minimize this adverse event, it is still wise to double-check the mouthpiece prior to MDI activation.

To optimize *maintenance* use of the MDI, the canister is shaken first and held in the inverted position. The patient exhales as much as comfortably possible to functional residual volume. The mouthpiece of the nebulizer is placed approximately 2 to 4 cm from the open mouth or, if a spacer device is used, the lips are placed around the *spacer* mouthpiece. The patient then activates the device at shortly after inspiration inhaling *slowly* (at 10 L/min), with the tongue and teeth as removed as possible to decrease oropharyngeal deposition. Inhalation is continued as long as possible and held 10 seconds, if possible. [148] The inhalation is repeated in 1 to 5 minutes to allow the medication's preliminary effects to enhance the penetration of the second treatment. One pediatric study in which full exhalation and breath-holding subsequent to inhalation were omitted still found improved outcome, probably because of enhanced compliance

with the easier instructions. [149]

In the *acute* exacerbation setting, in which the physician elects to use the MDI rather than nebulizer therapy, the following approach is suggested. A fresh canister is used (or the patient's own MDI can be used if adequate medication remains; see the "float test"-- Fig. 6-22). A spacer device (see below) can be used to maximize the therapeutic effect. The patient is instructed carefully on the correct technique as described previously. (Demonstration of the technique in front of a family member is helpful; often family members are quite eager to ensure optimal home care.) When treating bronchospasm, the patient should initially take up to 4 consecutive puffs of a beta-adrenergic drug, such as albuterol delivered through a spacer. One study found that 90% of subjects reached maximal bronchodilatation after 3 treatments (4 puffs/treatment, 30 minutes apart, 1.2 mg total) of albuterol by MDI with spacer. [134] Patients failing to respond adequately should receive additional doses. The optimal interval of dosing has yet to be determined, and recommendations range considerably.

Failure of home therapy with the same medication does not preclude successful emergency department therapy for at least three reasons: (1) inadequate patient compliance, (2) use of an empty canister, and (3) inadequate dosing. Some patients have been cautioned against overuse of the MDI and may develop a fear of taking more than the ordered 2 puffs. Both physicians and patients should be comforted to know that double the current recommended maintenance dose, much less the occasional extra puff, is quite safe. Nonetheless, the patient and family should be cautioned that increased inhaler requirement indicates an exacerbation of the underlying disease requiring more aggressive therapy; this accelerated disease condition has been associated with increased risk of death or near death from asthma. [150]

**Spacer Devices**

Spacer devices serve as adjuncts to successful use of the MDI for the large subgroup of inhaler users with suboptimal technique. One study demonstrated a nine-fold reduction in oropharyngeal deposition and a greater than double increase in drug deposition over the whole lung with one of these instruments. [139] Additionally, spacers reduce the incidence of oral candidiasis for steroid inhalers by decreasing oropharyngeal deposition. [132]

Essentially, there are two types of spacers: (1) the tube and (2) the airbag type. The simple toilet roll tube, the plastic cola bottle, or the commercially available AeroChamber (Monaghan Medical Corp., Plattsburgh, NY; distributed by Forest Pharmaceuticals, Inc., St. Louis) and Ace Spacer (Center Laboratories, Port Washington, NY) are basically *fixed tubes* of various lengths and shapes (Fig. 6-23) . This type of inhaler can be constructed from common ventilator tubing and, when coupled with a mask (Fig. 6-24) (Figure Not Available) , has been used in the treatment of children as young as 1 month. [136] Recently, the AeroChamber device has been marketed complete with a mask for aiding delivery in the very young (AeroChamber with mask--small) or the old and infirm (AeroChamber with mask--large). This system maximizes drug delivery to those who can tolerate a face mask but cannot use the mouthpiece of the standard AeroChamber

device.

The inhaler mouthpiece is checked for the absence of foreign material, shaken well several times, and placed at one end of the spacer; the patient's mouth is at the other. The patient or parent activates the MDI; only a single puff is recommended. The patient breathes in slowly, exhales to the air, and takes several additional slow breaths from the tube. When the AeroChamber is used, the device makes a whistling noise if the patient breathes in too quickly. When the mask is used with the AeroChamber spacer, the mask is placed gently against the face to cover the nose and mouth (making a good seal), and the same process is followed. Crying children are still able to breathe through the system, and the facial contact should be maintained after MDI activation until several breaths are taken. (When the spacer is used with a corticosteroid MDI, the patient's face should be cleaned with soap and water to remove residue after use.)

Other adjuncts fall into the *airbag* group, wherein the inhaler is either attached to or placed within an air-filled bag. The canister is activated, and the patient subsequently breathes in and out of the bag. An airbag-type spacer can be constructed by cutting a hole in the permanently sealed end of a quart-size plastic bag with a zipper closure, placing the inhaler shell orifice in the small hole, and taping the plastic tightly around the shell. The canister is removed; the bag is inflated with air; and the canister is replaced, activated, and promptly removed. The shell then acts as a mouthpiece, and the patient breathes in and out of the bag four to five times. [151]

### Complications

In the 1960s, MDIs were blamed for excessive deaths in the asthmatic population. There is no proven causal relationship between MDI use and an increased risk of death. [152] However, increased beta-agonist use, suggesting disease exacerbation, has been *associated* with an increase in mortality. [150]

Some patients may be sensitive to the preservatives and lubricants contained in MDIs. Multidose dry powder inhalers, such as the Bricanyl Turbuhaler, may overcome this difficulty. [153]

Some treatment failures also can be attributed to untimely exhaustion of the drug contained in the inhaler, which catches the patient unaware. A simple method to assess drug quantity involves observation of canister flotation in a bowl of water (see Fig. 6-22). One author [154] challenges the efficacy of this technique and recommends calculating the number of inhalations remaining in the canister (200 inhalation capacity for most beta-agonist MDIs).

Oral candidiasis is a complication of inhaled steroids and can be controlled or eliminated by the use of spacers or by activating the MDI at a distance, as discussed previously.

### Handheld Nebulizer Use

**Equipment**

Nebulizers work on two principles. One type, based on the Bernoulli effect, uses $O_2$ or air at a flow rate of 5 to 10 L/min to aerosolize a liquid from a reservoir and carry the particles of medication through a tube and into the patient's upper respiratory tract. A second type of nebulizer produces an aerosol using the ultrasonic action of piezoelectric crystals to create the medicated mist. Those employing the Bernoulli effect are commonly used, and several manufacturers supply acorn-type reservoir nebulizers. Larger reservoir jet nebulizers are available for providing continuous nebulization (e.g., the HEART nebulizer, Vortran Medical Technology Inc., Orangevale, Calif).

**Procedure**

As with the MDI, patient compliance with correct nebulizer technique is poor. In the 1000-patient IPPB Trial Group Study, which compared IPPB and the simple nebulizer, compliance with the assigned regimen was approximately 55%. This degree of noncompliance occurred despite an intensive effort to obtain maximum compliance, wherein patients received repeated instruction and monthly visits by nurse practitioners over the 3 years of the study. [155]

For the procedure, a reservoir is filled with medication (most often a $beta_2$ -agonist, such as albuterol), along with normal saline as a liquid carrier. The reservoir is then connected to the piezoelectric generator or to a source of propellant gas, either air or $O_2$ at 5 to 10 L/min. The aerosol is delivered via a mouthpiece or a ventilation mask to the patient's upper respiratory tract. The patient inhales slowly and deeply, and does so repeatedly, until the onset of audible nebulizer sputtering indicates that medication delivery has ceased [156] or until intolerable side effects intervene. The optimal dosage and frequency of $beta_2$ -agonists via nebulizer is still undetermined. Actual drug delivery depends on many variables, including equipment, technique, and the patient's clinical condition. Continuous beta-agonist nebulization therapy has been used for several years in the pediatric population. However, recent studies [157] [158] suggest only marginal benefits of continuous nebulization of albuterol (at rates of 5 mg/hour and 15 mg/hour, respectively) in patients presenting with severe obstruction. Although no adverse affects of continuous albuterol nebulization were exhibited in these studies, an earlier study noted tachycardia with doses of 0.4 mg/kg/hour (30 mg/hour). [159]

Handheld nebulizers have been found to have less nasopharyngeal effect than the face-mask type. Tapping the sides of the reservoir releases droplets of medication that are trapped on the baffles. Enhanced deposition in the peripheral airways can be achieved using an increased flow rate to raise the fraction of appropriate-sized particles. [139]

**Complications**

Oxygen-powered nebulizers were considered to have contributed to the death of 5 patients who developed hypercarbia after receiving $O_2$ -powered nebulized salbutamol for severe respiratory distress. Two died despite intubation. [138] Transient, unpredictable

decreases in Pa$O_2$ with nebulizer use [160] have been found to be of significance only for the most severely compromised patient and can be recognized and managed by exercising the proper vigilance due in such a critical condition. [161] Cautious administration of supplemental $O_2$ during nebulizer therapy appears to minimize this effect. [162]

## Conclusions

There appears to be little controversy in the current literature as to the safety, efficacy, and superiority of the inhalant route of therapy for acute bronchospasm. Despite strong evidence of the advantages of MDIs (combined with spacers) compared with nebulizers for the treatment of acute reactive airway disease, nebulization remains the most widely used modality in most emergency departments. The MDI, when used correctly, is cheaper, less prone to contamination, and far more convenient for patients both in and out of the hospital.

The appearance of a patient suffering from an exacerbation of reactive airway disease should be viewed as an opportunity for medical personnel to observe and correct the patient's use of the MDI--a powerful therapeutic method when used correctly. Failure of the patient to demonstrate correct use of the MDI suggests the need to implement a spacer device. The spacer is a low-cost, highly efficient device that can pay for itself many times over in reduced future visits. Correction of poor technique and treatment of the acute process with the MDI will reduce the impression that a magical property is inherent in nebulizer use, simplify home therapy for many, and decrease medical costs.

# Chapter 7 - Mechanical Ventilation

**William Durston ,John J. Kelly** , **Barry J. Burton**

Once intubation has been undertaken and the tracheal tube has been secured in proper position, most patients who require prolonged ventilation will be placed on a ventilator. Ventilators have become increasingly technical since the mid-1980s, yet the basic functions prevail. The purpose of this chapter is to provide a usable and practical guide to allow the clinician to properly institute mechanical ventilation. The discussion includes indications for mechanical ventilation, ventilator setup and use, settings and features, and complications that may arise while using mechanical ventilation.

## INDICATIONS FOR MECHANICAL VENTILATION

The principal indication for mechanical ventilation is respiratory failure. Respiratory failure can be defined in terms of arterial blood gases, although criteria based on pulmonary mechanics have also been proposed. The indications for mechanical ventilation are somewhat debatable and must be applied selectively in individual situations, but general indications are summarized in Table 7-1 . Abbreviations used throughout this discussion are found in Table 7-2 .

Respiratory failure in adults is usually defined as either a $Pa_{O2}$ <60 mm Hg while the patient is breathing the maximum oxygen ($O_2$ ) concentration achievable by mask or

| TABLE 7-1 -- Indications for Mechanical Ventilation |
| --- |
| Blood gas criteria |
|    $Pa_{O2}$ <55-60 mm Hg on maximum $Fi_{O2}$ by mask |
|    $Pa_{CO2}$ >50 mm Hg and pH <7.30 |
| Blood gas criteria in neonates |
|    Patient on CPAP of 5-8 cm $H_2$ O and $Fi_{O2}$ up to 0.80 |

| |
|---|
| $Pa_{O_2}$ <55-60 mm Hg |
| $Pa_{CO_2}$ >60 mm Hg |
| pH <7.25 |
| Criteria based on pulmonary mechanics |
| Vital capacity <10 mL/kg |
| $FEV_1$ <10 mL/kg |
| MIF <25 cm $H_2O$ |
| $V_D/V_T$ >0.6 |
| Indications other than respiratory failure |
| Need for hyperventilation |
| Increased intracranial pressure |
| Tricyclic antidepressant overdose |

| |
|---|
| Hypothermia |
| Mechanical ventilation used as means of core rewarming |
| Prophylactic postoperative mechanical ventilation |
| In postoperative patients with shock, morbid obesity, COPD, neuromuscular disease, or other debilitating illness or following cardiothoracic surgery |

a $Pa_{CO2}$ >50 mm Hg with a pH <7.30. These criteria must be modified by the clinical situation. For example, a patient with chronic obstructive pulmonary disease (COPD) who retains carbon dioxide (a *CO2 retainer*) but who has an acute loss of bicarbonate due to a diarrheal illness, might have a $Pa_{O2}$ value of 55 mm Hg, a $Pa_{CO2}$ of 50 mm Hg, and a pH of 7.32 and yet be quite stable from a pulmonary standpoint. A young asthmatic with the same blood gas values might be in need of immediate intubation and mechanical ventilation. [1]

In addition to arterial blood gases, other indices of pulmonary function may be helpful in determining whether a patient requires mechanical ventilation. In adults, a respiratory rate of >35 to 40 breaths/min usually cannot be sustained for prolonged periods, and if this rate is required to maintain a normal pH or $Pa_{CO2}$ , tachypnea may be an indication for mechanical ventilation. A forced expiratory volume in 1 second ($FEV_1$ ) of <1000 mL or <10 mL/kg indicates severe airway obstruction and, if not readily reversible, predicts that the patient may need ventilatory assistance. A vital capacity (VC) <10 mL/kg and a maximum inspiratory force (MIF) <25 cm $H_2$ O are other indications that the patient will not be able to adequately maintain independent ventilation. Similarly, a dead space to tidal volume ratio ($V_D/V_T$) of >0.6 implies a high minute volume requirement and a need for ventilatory assistance in most patients.

Respiratory failure in adults is usually caused by primary pulmonary disease, cardiac disease, neuromuscular disease, drug overdose, or a combination of these conditions. In neonates, respiratory failure usually results from hyaline membrane disease, meconium aspiration, sepsis, or congenital cardiopulmonary anomalies. Respiratory failure in children beyond the neonatal period is most often due to respiratory infections, asthma, or accidents such as near-drowning or chemical aspiration. Indications for mechanical ventilation based on pulmonary mechanics are difficult to apply in infants and children because the patients are usually unable to cooperate in measuring VC, $FEV_1$ , and MIF. Respiratory rates of 35 to 40 breaths/min are normal in neonates and common in febrile children (see Chapter 70) , and tachypnea alone is not an indication

for mechanical ventilation.

The blood gas criteria for respiratory failure in infants are similar to those in adults, except that more deviation from the physiologic norm may be allowed before mechanical ventilation is instituted. Typical blood gas criteria for respiratory failure in infants cited in the literature include a pH <7.25, a $Pa_{CO2}$ >60 mm Hg, and a $Pa_{O2}$ <55 to 60 mm Hg. Infants who are hypoxemic but not hypercapnic may first be tried on continuous positive airway pressure (CPAP) with high inspired $O_2$ concentrations before mechanical ventilation is instituted. [2] [3] [4] As with adults, other clinical factors must be weighed in deciding whether to institute mechanical ventilation. Apneic or bradycardiac periods may warrant ventilatory support, and low-birth-weight or premature infants are more likely to require mechanical ventilation.

In the absence of respiratory failure, there are few other indications for mechanical ventilation. Flail chest was formerly considered one of these. The concept of alkalotic apnea for internal pneumatic stabilization of the critically "crushed chest" was proposed in 1956 by Avery and colleagues, who found that positive-pressure ventilation was more effective and humane in the treatment of flail chest than were the older methods of external stabilization with Hudson traction and towel clips. [5] For 2 decades following

| **TABLE 7-2** -- Abbreviations Used in This Chapter | |
| A-a$_{DO2}$ | Alveolar-arterial oxygen difference |
| ARDS | Adult respiratory distress syndrome |
| Ca | Oxygen content of systemic arterial blood |
| Cc | Oxygen content of pulmonary capillary blood |
| Cv | Oxygen content of mixed venous blood |

| | |
|---|---|
| COPD | Chronic obstructive pulmonary disease |
| CPAP | Continuous positive airway pressure |
| f | Respiratory rate or frequency |
| $FEV_1$ | Forced expiratory volume in 1 second |
| $FIO_2$ | Percent oxygen content of inspired gas |
| HFV | High-frequency ventilation |
| IMV | Intermittent mandatory ventilation |
| IRV | Inverse ratio ventilation (I:E ratio >1) |
| MIF | Maximum inspiratory force |
| MVV | Maximum voluntary minute volume |
| $P_{ACO_2}$ | Alveolar carbon dioxide tension |
| $Pa_{CO_2}$ | Arterial carbon dioxide tension |

| | |
|---|---|
| $P_{AO_2}$ | Alveolar oxygen tension |
| $Pa_{O_2}$ | Arterial oxygen tension |
| $P_{ECO_2}$ | Tension of carbon dioxide in mixed expired air |
| PEEP | Positive end-expiratory pressure |
| Qs/Qt | Shunt fraction (ratio of right-to-left shunt to total pulmonary blood flow) |
| R | Respiratory quotient (ratio of carbon dioxide produced by the body to oxygen consumed) |
| SIMV | Synchronized intermittent mandatory ventilation |
| $V_A$ | Alveolar ventilation |
| $V_A$ | Alveolar minute ventilation |
| VC | Vital capacity |
| $V_{CO_2}$ | Carbon dioxide production per minute |
| $V_D$ | Dead space volume |

| $V_E$ | Expired minute volume |
|-------|-----------------------|
| $V_T$ | Tidal volume |

Avery's report, it was largely accepted that most patients with flail chest segments should be treated with mechanical ventilation to minimize chest wall motion caused by spontaneous respiratory effort and to allow the fractured ribs to heal. More recently, it has been recognized that patients who have flail segments but who do not meet usual blood gas criteria for respiratory failure do better if treated only with pain control, including epidural and intercostal blocks, than if treated with mechanical ventilation. [6]

Mechanical ventilation may be instituted in the absence of respiratory failure in patients who require hyperventilation. In patients with increased intracranial pressure, hyperventilation to a $Pa_{CO2}$ of 30 to 35 mm Hg has been advocated to modestly reduce cerebral blood volume and intracranial pressure. [7] Hyperventilation has also been proposed to produce a respiratory alkalosis as a means of preventing seizures and ventricular dysrhythmias in patients suffering from tricyclic antidepressant overdose. [8]

In severely hypothermic patients, the administration of warm nebulized air is an adjunctive means of core rewarming. [9] Although such patients usually require mechanical ventilation for other reasons, the need for rewarming might be considered an additional indication. Postoperative mechanical ventilation is also used "prophylactically" in certain surgical patients who are at high risk for the development of respiratory failure, atelectasis, or pneumonia. Conditions that may place a patient in a high-risk category include shock, morbid obesity, COPD, neuromuscular disease, or other debilitating illnesses. Patients also are at increased risk for the development of respiratory complications following cardiothoracic surgery. [10]

There are no absolute contraindications to mechanical ventilation. Some consider COPD with chronic $CO_2$ retention to be a relative contraindication, because patients with this condition are notoriously difficult to wean back to spontaneous breathing. When the COPD patient presents with respiratory failure, however, the condition has usually been precipitated by an acute process, such as a pulmonary infection, which can be reversed while the patient receives ventilatory assistance. The complication rate is unusually high in patients with asthma during mechanical ventilation as a result of the high pressures required to ventilate these patients. [11] Hence, combining positive-pressure ventilation with pharmacologic sedation and/or muscle relaxation may be required. Although barotrauma should be anticipated in treating severe asthmatics with mechanical ventilation, mechanical ventilation nonetheless may be life saving. In some patients with terminal illness or chronic debilitating disease without hope for clinical recovery, a decision not to initiate mechanical ventilation may be made on moral grounds.

# TYPES OF VENTILATORS

Mechanical ventilators manufactured by more than a dozen companies are currently available in the United States; most manufacturers offer several different models. Despite the diversity of these machines, they may be grouped and classified according to a few basic characteristics that describe their operation.

## Inspiratory Flow

There are basically 2 types of inspiratory flow patterns built into modern ventilators. The inspiratory flow either is constant during the inspiratory cycle or varies from the start to the end of the cycle. In general, ventilators with constant flow are called *flow generators*, whereas ventilators with variable flow are classified as *pressure generators*. [12] In a constant- *flow* generator, a high-pressure gradient is established between the ventilator and the patient. The machine is built with a high internal resistance so that changes in the resistance and compliance of the patient's airways make relatively little contribution to the total resistance of the system. The result is a constant, or square wave, flow pattern (Fig. 7-1 (Figure Not Available) *A*). In a constant- *pressure* generator, the machine develops a constant pressure that is only slightly above the pressure in the patient's airways. An exponential flow pattern results, with flow approaching zero as the patient's airway pressure approaches the pressure from the ventilator (Fig. 7-1 (Figure Not Available) *B*).

It is apparent that constant-flow generators and constant-pressure generators are not conceptually different but rather are the opposite ends of a spectrum. By reducing internal resistance and machine pressure, a constant-flow generator can be converted into a constant-pressure generator. A sine wave flow pattern is also available on some ventilators (Fig. 7-1 (Figure Not Available) *C*). Such a flow pattern is produced by gas being driven by a piston on an eccentric cam.

The flow patterns of ventilators are of more interest to bioengineers than to clinicians, except that some modern ventilators have controls that allow the operator to switch from one flow pattern to another. As discussed in the section on ventilator settings, by changing the flow pattern, one may sometimes produce small but significant improvements in ventilation of the patient.

## Cycling

In addition to being classified according to their inspiratory flow characteristics, ventilators are classified according to the factor that determines when the ventilator cycles from the inspiratory phase to the expiratory phase. Basically, ventilators can be described as pressure-cycled, volume-cycled, or time-cycled.

### Pressure-Cycled

In pressure-cycled ventilators, the inspiratory phase is terminated, and expiration begins

when a preset pressure limit is reached. The tidal volume ($V_T$) received by the patient is not set directly but depends on the set pressure limit and the patient's chest and lung compliance and airway resistance. As long as the patient's compliance and resistance do not change, the $V_T$ will be the same with each breath. If the patient's compliance falls or resistance increases, the $V_T$ will also fall, and hypoventilation may result.

Because of the problem of a changing $V_T$ caused by changing patient compliance, pressure-cycled ventilators have been largely replaced by volume- or time-cycled ventilators for mechanical ventilation in adults. Pressure-cycled ventilators still have certain advantages, however. They are less expensive than volume- and time-cycled machines. They are more compact and can be run by compressed gas sources without the need for an electrical source, making them well suited for ambulance transport. For reasons discussed later, pressure-cycled machines also remain popular for ventilating infants and neonates.

**Volume-Cycled**

In volume-cycled ventilators, inspiration is terminated and expiration begins when a preset $V_T$ is delivered. The gas is usually delivered from a compressible bellows. Since the introduction of the Puritan-Bennett MA-1 volume ventilator in 1968, volume ventilators have become the standard for mechanical ventilation in adults. They have an important advantage over pressure-cycled ventilators: delivery of a relatively constant $V_T$ despite changes in the patient's compliance. Even with volume-cycled machines, however, the delivered $V_T$ falls slightly if the patient's compliance falls. This is because although a constant volume is delivered from the ventilator bellows, as the patient's lungs become stiffer, more of this gas is lost to expansion of the ventilator tubing. This phenomenon becomes very important in infants. The compliance of the child's chest and lungs may be less than the compliance of the ventilator tubing, and more gas will go to expansion of the tubing than to ventilation of the patient.

Most modern volume-cycled ventilators have adjustable secondary pressure limits such that when the airway pressure exceeds the set limit, inspiration is terminated. Thus, volume-cycled ventilators may function as pressure-cycled ventilators when the pressure limit is set at a low enough level.

**Time-Cycled**

In time-cycled ventilators, inspiration is terminated and expiration begins after a preset time has elapsed. The $V_T$ that is delivered is determined by the integral of the inspiration flow-inspiratory time curve. Time-cycled ventilators resemble volume-cycled machines in that they deliver a relatively constant $V_T$ despite changes in the patient's compliance. They may also function as pressure-limited ventilators when

the secondary pressure limits are adjusted. Time-cycled ventilators are becoming increasingly popular. They allow great flexibility in adjustment of the inspiratory-to-expiratory ratio, and their internal circuitry is such that they can be

manufactured at a lower cost than most volume-cycled machines.

## CHOOSING VENTILATOR SETTINGS

To optimize ventilator therapy, the physician must understand the capabilities of the ventilator, the pathophysiology of the patient, and how to match the ventilator settings to the patient's condition to achieve the desired results. In this section, the rational choice of ventilator settings is discussed. Not all of the settings described in this section are available on every ventilator. To learn the capabilities of a given ventilator, the physician should consult the operating manual supplied with the particular machine. A summary of recommended initial ventilator settings is provided in Table 7-3 .

### Rate and Tidal Volume

The two most important settings on a volume-cycled ventilator (and those that are usually set first) are the rate and $V_T$. To provide an understanding of the way in which the rate and $V_T$ determine alveolar ventilation and the arterial $CO_2$ tension ($Pa_{CO_2}$ ), it is necessary to briefly review some aspects of pulmonary physiology.

#### Minute Volume and Alveolar Ventilation

The volume of air that moves in and out of a patient's lungs per minute is termed the minute volume ($V_E$). Minute volume is the product of $V_T$ and respiratory frequency or rate (f):

$$V_E = V_T \times f \; [1]$$

Tidal volume can be further broken down into alveolar ventilation ($V_A$) and dead space ventilation ($V_D$):

$$V_T = V_A + V_D \; [2]$$

In healthy young persons, the anatomic dead space can be accounted for by the trachea and the larger airways and is approximately 2.2 mL/kg of lean body weight. In disease states, in addition to the anatomic dead space, there is also a variable amount of "pathologic" dead space corresponding to ventilated alveoli and respiratory bronchioles that are not adequately perfused. The sum of the anatomic and pathologic dead spaces is often referred to as the physiologic dead space.

Alveolar minute ventilation ($V_A$) is the product of rate times $V_T$ minus dead space:

$$V_A = (V_T - V_D) \times f \; [3]$$

Alveolar minute ventilation and the rate of $CO_2$ production by the body ($V_{CO_2}$ ) determine the partial pressure of $CO_2$ in the alveoli ($PA_{CO_2}$ ), which is approximately equal to the systemic arterial $CO_2$ tension ($Pa_{CO_2}$ ). This relationship is shown in

equation 4:

$$PaCO_2 \; PACO_2 = k \times (V_{CO_2} / V_A) \; [4]$$

where the value of the constant (k) is 0.863 when the partial pressure of $CO_2$ is measured in millimeters of mercury at 37 °C saturated with water vapor, $V_{CO_2}$ is measured in milliliters per minute, and $V_A$ is measured in liters per minute.

Using equations 3 and 4, one can work through the example of an average 70-kg man with a typical spontaneous $V_T$ of 500 mL, respiratory rate of 12 breaths/min, $CO_2$ production of 200 mL/min, and dead space of 150 mL, and see that the result is a normal $Pa_{CO_2}$ :

$$V_A = (0.500 - 0.150) \times 12 \; 4.2 \; L/min$$

and

$$Pa_{CO_2} = 0.863 \times (200/4.2) = 41.0 \text{ mm Hg}$$

If the same 70-kg man were to develop respiratory failure purely on a neurologic basis, without any change in

| TABLE 7-3 -- Recommended Initial Ventilation Settings | | |
| --- | --- | --- |
| **Parameter** | **Recommended Setting** | **Comment** |
| Tidal volume | 10-15 mL/kg | 8 to 12 mL/kg in infants (see section on rate and tidal volume) |
| Rate | 12-14 breaths /min | Starting rates of 25 to 30/min used in infants; rates of 18/min used in adults when hyperventilatation is indicated or when $V_D/V_T$ is very high (see section on rate and tidal volume) |

| | | |
|---|---|---|
| Fi$_{O_2}$ | 0.5-1.0 | To avoid oxygen toxicity, reduce Fi$_{O_2}$ to <0.5 as soon as possible, guided by blood gas analysis results |
| Ventilator mode | Assist control, IMV, or SIMV | (See section on ventilator mode) |
| PEEP | None | Start with PEEP of 5 cm $H_2O$ and increase in 5 cm $H_2O$ increments if Pa$_{O_2}$ <60 mm Hg with Fi$_{O_2}$ 0.50 (see section on PEEP and CPAP) |
| Inspiratory waveform | Square wave | (See section in inspiratory flow) |
| Inspiratory flow | 50 L/min | 8 to 15 L/min in infants (see section on inspiratory flow rate) |
| Inspiratory pause | None | (See section on inspiratory pause) |
| I:E ratio | 1:2 | (See section on I:E ratio) |
| Peak pressure | 50 cm $H_2O$ | With pressure-cycled ventilators, starting pressures of 20-30 cm $H_2O$ should be used in infants and in adults with normal compliance (see section on peak pressure) |
| Expiratory retard | None | (See section on expiratory retard) |

| | | |
|---|---|---|
| Sighs | None | (See section on sighs) |
| Humidifier temperature | 35°C | Use higher temperature (40°C) for rewarming hypothermic patients, lower temperature for cooling febrile patients |

his dead space or $CO_2$ production, one might assume that the appropriate ventilator settings would be a $V_T$ of 500 mL and a rate of 12 breaths/min. It has been found empirically, however, that when patients with $V_T$ values that are in the normal range for spontaneous breathing are ventilated, atelectasis and hypoxemia develop. [10] This can be prevented by ventilating patients at higher $V_T$ levels, in the range of 10 to 15 mL/kg. Also, mechanical ventilation alters the normal ventilation-perfusion relationship in the lungs, causing relatively greater ventilation of the less-well-perfused upper lung regions, which in turn results in an increase in physiologic dead space. [13] The magnitude of this effect is equivalent to roughly doubling the predicted dead space. [14]

Returning to the case of our 70-kg man, assuming a physiologic dead space on the ventilator of 300 mL, a desired $V_T$ of 12 mL/kg (850 mL), and a desired $Pa_{CO_2}$ of 40 mm Hg, one can use equations 3 and 4 to determine the desired ventilator rate:

$Pa_{CO_2} = 0.863 \, (V_{CO_2} / V_A)$

$40 = 0.863 \times (200/V_A)$

To determine $V_A$:

$V_A = (0.863 \times 200)/40$

$= 4.3 \, L/min$

By putting this value for $V_A$ into equation 3, the value of f can be determined:

$V_A = (V_T - V_D) \times f$

$4.3 = (0.850 - 0.300) \times f$

$f = 4.3/(0.850 - 0.300)$

= 7.8 breaths/min

8 breaths/min

In practice, such a low rate is rarely prescribed as the initial ventilator setting. Most patients requiring mechanical ventilation have more than normal dead space, and it is usually safer to risk mild hyperventilation than hypoventilation. Starting rates of 12 to 14 breaths/min are recommended for most adult patients.

**Changes in $PaCO_2$ as a Result of Changes in Rate and Tidal Volume**

Once a patient has been placed on a ventilator at a rate and $V_T$ that are deemed appropriate, it is necessary to check arterial blood gas values to be sure that the patient is being adequately ventilated and oxygenated. Arterial samples for blood gas analyses are customarily drawn 15 minutes after the initiation of mechanical ventilation or after changes in ventilator settings. This interval is supported by indirect evidence suggesting that blood gases reach equilibrium within 15 minutes after ventilator changes in most patients with severe pulmonary disease and much sooner in patients with normal lungs. [15] [16] In most patients, achieving a normal $Pa_{CO2}$ (36 to 44 mm Hg) is the goal. In some cases, however, a higher or lower $Pa_{CO2}$ is desired. For example, most experts warn against rapid reduction of $Pa_{CO2}$ to normal in patients with chronic $CO_2$ retention. The resultant alkalemia may have many undesirable consequences, including diminished cardiac output, diminished cerebral blood flow, hypokalemia, hypocalcemia with associated seizures, increased airway resistance, and a shift in the hemoglobin-oxygen dissociation curve to the left with impaired release of $O_2$ to the tissues. [13] However, in patients with increased intracranial pressure due to trauma, infection, or cerebrovascular accident, a slightly lower than normal $Pa_{CO2}$ may be desired to help lower intracranial pressure. [7]

Whatever the desired $PaCO_2$, if the measured $Pa_{CO2}$ differs from the desired level, the ventilator rate or $V_T$ must be adjusted accordingly. One can easily calculate the amount of change in ventilator settings needed to produce the desired change in $Pa_{CO2}$ using the following relationship:

$$V_{E2} = (Pa_{CO2}\ 1\ /Pa_{CO2}\ 2\ ) \times V_{E1}\ [5]$$

where $V_{E2}$ is the desired minute volume, $V_{E1}$ is the present minute volume, $Pa_{CO2}\ 2$ is the desired $Pa_{CO2}$, and $Pa_{CO2}\ 1$ is the present $Pa_{CO2}$. Strictly speaking, $Pa_{CO2}$ varies inversely with alveolar minute ventilation and not with total minute ventilation, which includes both alveolar ventilation and wasted, dead space ventilation. It has been observed empirically, however, that the ratio of $V_D/V_T$ remains relatively constant despite changes in $V_T$. [17] Thus, equation 5 holds true whether rate or $V_T$ or both are altered. As an example, suppose that a 70-kg patient is being ventilated at a rate of 10 breaths/min with a $V_T$ of 900 mL. The observed $Pa_{CO2}$ is 50 mm Hg, and the desired $PaCO_2$ is 30 mm Hg. The desired minute volume is calculated as follows:

$V_{E2}$ = (50/30) × 9.0 L/min

ISOdia = 15 L/min

To obtain a $Pa_{CO_2}$ of 30 mm Hg, the rate could be increased to 16 and the $V_T$ to 940 mL, giving a new minute volume of 15 L/min.

**Adding Dead Space**

Some patients who are placed on ventilators and who are allowed to trigger the machine themselves, as in the assist control mode, will spontaneously hyperventilate. If the $Pa_{CO_2}$ drops as low as 25 to 30 mm Hg in a patient who is used to a normal $Pa_{CO_2}$ , the same complications may develop as described previously for rapidly lowering the $CO_2$ to normal in a chronically hypercapnic patient. An approach that may be useful in dealing with patients who spontaneously hyperventilate is to add dead space to the ventilator tubing so that the patient rebreathes some of the expired air. A formula has been developed that predicts the amount of dead space that must be added to give a desired increase in $Pa_{CO_2}$ . [18] This formula is somewhat complicated, though, and requires determination of the concentration of $CO_2$ in the expired air. Empirically, it has been found that the addition of 50 mL of dead space leads to an increase in $Pa_{CO_2}$ of approximately 5 mm Hg in most patients.

Another approach to raising the $Pa_{CO_2}$ in a patient who spontaneously hyperventilates is to add $CO_2$ to the inspired air. A rise of 1% in the inspired $CO_2$ concentration leads to a rise in $Pa_{CO_2}$ of approximately 5 mm Hg. [19] The disadvantage of using this method rather than adding dead space is that it requires an expensive piece of additional equipment, the $CO_2$ mixer. Paradoxically, it has been found that increasing the $Pa_{CO_2}$ by either method leads to a rise, rather than a decline, in $Pa_{O_2}$ .

The paradoxical rise in $Pa_{O_2}$ seems to be a result of the

increased cardiac output that occurs with normalization of the $Pa_{CO_2}$ . The problem with adding either dead space or inspired $CO_2$ is that the patient may hyperventilate even more, returning the $Pa_{CO_2}$ to harmfully low levels. If this occurs, the patient should be sedated or changed to a different ventilator mode, as will be discussed subsequently.

**The Dead Space-to-Tidal Volume Ratio**

As noted earlier, in addition to their anatomic dead space, patients with pulmonary disease have variable amounts of pathologic dead space. The $V_D/V_T$ ratio is useful to follow as an index of the severity of a patient's pulmonary disease. The normal $V_D/V_T$ ratio is 0.20 to 0.35. [20] Patients with $V_D/V_T$ ratios 0.6 usually need ventilatory assistance, because they require large minute volumes to maintain adequate alveolar ventilation. The $V_D/V_T$ ratio may be calculated using the Bohr equation, as follows:

$$V_D/V_T = (P_{ACO2} - P_{ECO2})/P_{ACO2} \quad [6]$$

where $P_{ECO2}$ is the partial pressure of $CO_2$ in mixed expired air and $P_{ACO2}$ is the partial pressure of $CO_2$ in alveolar air, which is assumed to be the same as $Pa_{CO2}$. To use this equation, one must have access to a $CO_2$ analyzer. Although these analyzers are commercially available, they are not standard equipment in all emergency departments or intensive care units. For this reason, a graph has been constructed from which $V_D/V_T$ can be determined if the patient's minute ventilation and $Pa_{CO2}$ (Fig. 7-2) (Figure Not Available) are known. [21] The graph assumes a normal $CO_2$ production of 200 mL/min. Although critically ill patients tend to have higher rates of $CO_2$ production, it has been found empirically that $V_D/V_T$ ratios determined by the graph correlate well with $V_D/V_T$ ratios measured directly in patients in intensive care units. [21] The graph can also be used to predict the necessary minute ventilation to produce a desired $Pa_{CO2}$ in a patient with a known $V_D/V_T$ ratio.

**Compliance**

Measurement of pulmonary compliance is useful in following the progression of a patient's pulmonary disease as well as in determining the optimal $V_T$ and level of positive end-expiratory pressure (PEEP--see the following discussion). Compliance is defined as change in volume over change in pressure:

$$Compliance = DeltaV/DeltaP \quad [7]$$

Total pulmonary compliance can be subdivided into the compliance of the lung and the compliance of the chest wall. For practical purposes in managing most ventilator patients, only the total compliance need be considered. Total compliance in a ventilator patient may be measured as either static compliance, which is the $V_T$ delivered divided by the plateau airway pressure after the patient has been held in full inspiration for 1 second, or as dynamic compliance, which is the $V_T$ divided by the peak airway pressure. (When measuring compliance in a patient on PEEP, one considers the change in pressure to be the difference between the peak or plateau inspiratory pressure and the PEEP level.)

In monitoring ventilator therapy, measurements of static compliance are usually preferred, because dynamic compliance is affected not only by the elastic recoil properties of the patient's chest wall and lungs but also by the patient's airway resistance. Normal static compliance in a healthy young adult undergoing general anesthesia is approximately 50 mL/cm $H_2O$. [22] It is believed that the $V_T$ that leads to the greatest total compliance is that which results in maximal recruitment of alveoli without overdistention. In most patients, the best compliance is found with $V_T$ values of 12 to 15 mL/kg. [23] In addition to being affected by $V_T$, compliance is also affected by PEEP and characteristics of inspiratory flow, as is discussed later.

**Set Tidal Volume vs. Delivered Tidal Volume**

As discussed, an advantage of volume- and time-cycled ventilators is that they deliver a relatively constant volume despite changes in the patient's compliance. One must remember that even with volume- and time-cycled ventilators, delivered $V_T$ will drop slightly if the patient's compliance goes down. This drop in delivered volume occurs because the ventilator tubing has compliance of its own. Although most of the gas mixture delivered by the ventilator bellows goes to expansion of the patient's lungs, a certain amount is lost to expansion of the ventilator tubing.

The compliance of the tubing varies from ventilator to ventilator. For a typical modern volume ventilator, such as the Bear-2, the compliance of the inflow circuit is 3 mL/cm $H_2O$. [24] To calculate the difference between the set $V_T$ and that actually received by the patient, one can multiply the pressure read from the inspiratory pressure gauge at the end of inspiration by the tubing compliance. For example, if the set $V_T$ is 850 mL and the peak inspiratory pressure is 30 cm $H_2O$, then the volume delivered to the patient is as follows:

Delivered volume = set volume - (tubing compliance × peak pressure)

= 850 - (3 × 30)

= 760 mL

The lower the patient's compliance, the higher the peak inspiratory pressure and the greater the amount of gas mixture that will be captured in the ventilator tubing.

**Tidal Volume and Rate in Infants**

Some controversy remains concerning the appropriate rate and $V_T$ for mechanical ventilation of infants. Some researchers recommend lower $V_T$ values, in the range of 8 to 12 mL/ kg, and correspondingly rapid rates of 25 to 30 breaths/min. [2] In neonates with hyaline membrane disease, rates as high as 60 to 100 breaths/min may be used in an attempt to synchronize the ventilator with the infant's own breathing pattern. [25] Other investigators recommend higher $V_T$ values (15 to 20 mL/kg) and lower respiratory rates (16 to 22 breaths/min). [26] Most ventilators used for adults and larger children are not capable of delivering the small $V_T$ values used in infants and neonates. (An exception is the Siemens-Elema Servo ventilator. [27] ) Therefore, special ventilators have been developed for neonatal intensive care. The compliance and dead space of the ventilator tubing and the valves have special importance in neonates. The total pulmonary compliance of a newborn with hyaline membrane disease may be 1 mL/cm $H_2O$, which is the same as the compliance of some ventilators designed especially for use in neonates. Thus, with each breath delivered by the machine, half of the volume expands the patient's lungs and the other half expands the ventilator tubing. This technical problem has to some extent hampered the development of volume ventilators for infants. [28] Another problem in infants and children is that leaks around uncuffed endotracheal tubes prevent accurate determination of volumes delivered to the lungs. Adequacy of ventilation must be ensured by clinical observation of chest excursions,

auscultation of breath sounds, and blood gas determinations. [29]

## Inspired Oxygen Concentration

After rate and $V_T$ have been set, the next variable that the physician usually sets is the inspired $O_2$ concentration ($Fi_{O2}$ ). The goal should be to deliver the lowest $O_2$ concentration that provides adequate arterial oxygenation. Adequate arterial oxygenation is difficult to define and may vary from patient to patient. Most experts recommend maintaining a $Pa_{O2}$ of 60 mm Hg, because this measurement corresponds to the shoulder on the normal hemoglobin-oxygen dissociation curve at which hemoglobin is 90% saturated with $O_2$ . Beyond this point, increases in $Pa_{O2}$ lead to relatively little improvement in hemoglobin saturation, whereas below this point, small decrements in $Pa_{O2}$ cause large drops in hemoglobin saturation. Conditions such as acidemia, fever, hypercarbia, and certain hemoglobinopathies result in a shift in the curve to the right so that at a $Pa_{O2}$ of 60 mm Hg, the hemoglobin will be <90% saturated. Thus a target $Pa_{O2}$ of 60 mm Hg may not be adequate in such compromised patients. [30]

### Oxygen Toxicity

When one is initiating mechanical ventilation, it is better to err on the side of a higher than necessary $Fi_{O2}$ than to risk making a patient hypoxemic. Values of $Fi_{O2}$ in the range of 0.50 to 1.00 are commonly prescribed as initial settings. With long-term ventilator support, however, a higher than necessary $Fi_{O2}$ may have serious adverse effects. The phenomenon of pulmonary $O_2$ toxicity has been recognized since the turn of the century, although the pathophysiology is still not completely understood. [31] The syndrome begins with tracheal irritation, cough, and chest pain, followed by diminished vital capacity and dyspnea. In the later stages, hypoxemia develops with associated alveolar edema and infiltrates on chest radiographs. Finally, as the process becomes irreversible, fibrosis of alveoli occurs.

Although the exact dose-time relationship of pulmonary $O_2$ toxicity has not been established, it is known that at atmospheric pressure, an $Fi_{O2}$ of 0.40 is well tolerated for 30 days or more, an $Fi_{O2}$ of 0.70 will lead to signs and symptoms of toxicity by 2 days, and an $Fi_{O2}$ of 1.00 leads to toxicity within 30 hours. [31] In general, an $Fi_{O2}$ of 0.50 should be considered potentially toxic if used for more than a few days.

In neonates, two other manifestations of $O_2$ toxicity may occur: retrolental fibroplasia and bronchopulmonary dysplasia. [32] [33] The dose-time relationship of $O_2$ administration to the development of these two conditions is even less well established than $O_2$ toxicity in adults. A multicenter cooperative study designed to develop guidelines for the safe administration of $O_2$ in neonates was unable to yield any firm recommendations. [34]

### The Alveolar-Arterial $O_2$ Difference

After the patient has been on a given $FI_{O2}$ for 15 minutes, arterial blood gases should be checked. Besides confirming the adequacy of arterial oxygenation, blood gas results

can be used to measure the efficiency of the lungs in oxygenating venous blood. One way to quantify how well the lungs are doing their job is to compare the $O_2$ concentration delivered to the alveoli with the $O_2$ tension in arterial blood. The difference between these 2 values is known as the alveolar-arterial $O_2$ difference (A-$aDO_2$ ). The arterial $O_2$ tension ($PaO_2$ ) is easily obtained by blood gas analysis, and the alveolar $O_2$ tension $PAO_2$ ) is calculated using the following alveolar air equation:

$$P_{AO_2} [F_{iO_2} \times (P_B - P_{H_2O})] - P_{ACO_2} \times F_{iO_2} /R \quad [8]$$

where $P_B$ is barometric pressure (760 mm Hg at sea level), $P_{H_2O}$ is the pressure of water vapor in the patient's lungs (47 mm Hg at 37 °C), and R is the respiratory quotient (assumed to be 0.8 unless it has been directly measured). The alveolar $CO_2$ partial pressure, $P_{ACO_2}$ , is assumed to be the same as the arterial $CO_2$ tension, $P_{aCO_2}$ . When the patient is breathing 100% $O_2$ , this equation simplifies to the following:

$$P_{AO_2} 713 - P_{aCO_2} /R \quad [9]$$

At room air, a further approximation that is easy to remember (for sea level calculations) is as follows:

$$P_{AO_2} 150 - 1.2 \times P_{aCO_2} \quad [10]$$

The normal A-$aDO_2$ is approximately 8 mm Hg in healthy young adults and 16 mm Hg in healthy 60 year olds with

the subjects breathing room air at atmospheric pressure. (The formula of 10 mm Hg plus the age in decades can be used to estimate the normal gradient). With increasing inspired $O_2$ concentrations, the normal value for A-$aDO_2$ increases, although not in a strictly linear fashion. The normal A-$aDO_2$ for a healthy young adult breathing 100% $O_2$ is 30 to 50 mm Hg. [35]

## Ventilator Mode

After rate, $V_T$, and $F_{iO_2}$ have been set, the next priority is to set the mode of ventilation. Although not all of the modes discussed in this section are available on all ventilators, most modern machines allow the operator to choose more than one mode. The airway pressure and flow characteristics of the different modes are shown diagrammatically in Figure 7-3 .

### Controlled Ventilation

In this mode, the patient is ventilated at the rate set by the operator. The patient cannot breathe between machine breaths. This mode may be used in an unconscious patient with depressed respiratory drive, in a heavily sedated patient, in a patient who has been paralyzed with drugs, or in a patient who is being deliberately hyperventilated. In this mode, alert patients may attempt to inhale against the closed inspiratory valve, resulting in apprehension, asynchronous chest movement, increased $O_2$ consumption and $CO_2$

production, and high peak pressures.

**Assist Control**

In this mode, the operator sets the minimum rate for the patient to be ventilated. If the patient makes no respiratory effort, the prescribed number of breaths will be delivered and no more. If the patient does try to breathe, the machine will deliver an extra breath with the same $V_T$ as the others, when the patient generates a sufficient inspiratory effort. The amount of negative inspiratory pressure that the patient must generate to trigger the machine is controlled by the operator. The sensitivity is set so that it is neither too difficult for the patient to initiate a breath (in which case the ventilator would actually be functioning in the control mode) nor too easy (in which case small movements by the patient might trigger the machine). The advantage of assist control over the control mode is that it allows the patient to regulate the minute volume in part. This mode is usually preferred in conscious patients. A disadvantage of assist control is that some patients spontaneously hyperventilate to an undesirable degree in this mode.

**IMV and SIMV**

Intermittent mandatory ventilation (IMV) was introduced in the early 1970s. [36] As in the assist control mode, the patient may breathe at a rate faster than the set ventilator frequency. With IMV, however, when the patient initiates a spontaneous breath, the machine offers no assistance, and the patient receives only the $V_T$ that is self-generated. This is usually smaller than the $V_T$ delivered by the ventilator. As in the assist control mode, the patient may determine the minute volume in part. An advantage of IMV is that there is less tendency for the patient to hyperventilate spontaneously. Also, because the patient must work harder to generate a spontaneous breath, it is believed that IMV may help to maintain the tone of the respiratory muscles. An additional potential advantage of IMV over assist control and controlled ventilation is that mean airway pressures tend to be lower in the IMV mode, resulting in less impedance to return of blood to the right side of the heart. [13] (See Complications of Mechanical Ventilation later in the chapter.) The IMV mode is particularly well suited for weaning a patient from mechanical ventilation. Over a period of hours to days, the IMV rate can be turned down gradually, so that the patient makes a smooth transition from depending mainly on the ventilator to breathing entirely independently. Some researchers have claimed that the use of IMV facilitates weaning in difficult patients, [36] although others have questioned the assertion that it speeds the weaning process. [37]

Older ventilators, such as the Puritan-Bennett MA-1, do not have IMV circuits built into them, but they may be converted to the IMV mode through the use of additional tubing and an independent $O_2$ source. This system wastes $O_2$, because the patient may breathe only a small fraction of the air-$O_2$ mixture that is continuously flowing through the IMV circuit. Newer ventilators have IMV circuits built into them so that gas flows through the IMV circuit only when the patient initiates a breath. Another problem that occurred with older IMV systems was that the ventilator sometimes delivered a $V_T$ just as the patient had completed a spontaneous inspiration. This so-called *stacking* of a machine breath on top of a spontaneous breath could lead to overdistention of the lungs and dangerously high peak pressures. This problem has been overcome by the

development of synchronized IMV (SIMV). This mode is the same as IMV except that the ventilator times the machine breaths to fall in a pause in the patient's spontaneous respiratory cycle or to coincide with the initiation of a spontaneous breath.

**Pressure Support**

This mode of ventilation, which was the basic mode on the old intermittent positive-pressure breathing machines, has been reintroduced, with some refinements, on some of the newer ventilators such as the Siemens Servo 900C. When the patient initiates a breath, the ventilator provides a constant inspiratory pressure, until inspiratory flow drops to 25% of the peak level. The patient determines the rate, and $V_T$ depends on the patient's compliance and the inspiratory pressure set by the operator. If the patient's compliance goes down, the $V_T$ will go down. The pressure support mode is obviously not desirable in patients with fluctuating ventilatory drive or pulmonary mechanics. It has been found useful, however, in patients with stable pulmonary disease and in patients being weaned from mechanical ventilation. In such patients, pressure support results in better patient comfort, slower spontaneous ventilatory rates, less patient work, and lower peak airway pressures than the SIMV mode. [38]

# PEEP

The acronym PEEP is used to denote positive end-expiratory pressure in a patient who is receiving assisted ventilation. In this mode, airway pressure is positive not only at end expiration but also throughout the respiratory cycle. When using PEEP, the ventilator can be in the control, assist control, IMV, SIMV, or pressure support modes. In older ventilators, application of PEEP involved cumbersome extra circuitry. In newer machines, the capability for PEEP is built in, and the level is set merely by turning a knob.

Theoretically, PEEP improves oxygenation by keeping alveoli open during expiration. Whether it actually works by this mechanism is a moot point. [39] What is known is that it leads to improved oxygenation and narrowing of the A-a$_{DO2}$ in most patients.

A generally accepted indication for PEEP is failure to achieve adequate oxygenation (i.e., Pa$_{O2}$ <60 mm Hg) with safe levels of inspired $O_2$ (i.e., Fi$_{O2}$ = 0.50). Other indications are more controversial. There is a prevalent philosophy in the surgical literature that PEEP has prophylactic value in preventing the respiratory distress syndrome or that it hastens its resolution. [40] One basis for this belief is that PEEP alters the appearance of infiltrates on chest films, making them appear less dense. In one study, skilled radiologists interpreted pre- and post-PEEP chest films differently in 25% of cases after patients had been on 10 to 20 cm $H_2$ O PEEP for only 15 minutes. [41] Thus some surgical intensive care units routinely use low levels of PEEP (5 to 8 cm $H_2$ O) in patients who require postoperative ventilation but who are not hypoxemic on safe levels of Fi$_{O2}$ . The prophylactic and therapeutic value of PEEP has been questioned in the medical literature, however. [42] In one large retrospective study, use of PEEP did not seem to improve survival in critically ill patients. [43] Animal studies designed to assess the influence of PEEP on pulmonary edema have shown either no change or an

increase in lung water after institution of PEEP. [44]

Determination of the optimal level of PEEP is also controversial. A conservative approach is to use a level of PEEP that is just enough to provide adequate arterial oxygenation with an $Fi_{O2}$ <50%. In patients requiring higher $Fi_{O2}$ levels, PEEP may be started at 5 cm $H_2O$ and may be increased in increments of 3 to 5 cm $H_2O$ at 15-minute intervals. At each new level, pulse and blood pressure, static compliance, peak airway pressure, arterial blood gas tension, and cardiac output should be measured and recorded. The pulmonary artery wedge pressure (PAWP) should probably also be measured, although it may not accurately reflect left ventricular filling pressure in patients on PEEP. [42] The $Fi_{O2}$ can usually be gradually turned down as PEEP is increased and the $A\text{-}a_{DO2}$ narrows. [45]

Most patients exhibit a fall in cardiac output at levels of PEEP above 12 to 15 cm $H_2O$. This drop is due in part to decreased venous return and can be at least partially overcome by expansion of intravascular volume. [46] Diminished myocardial blood flow at higher levels of PEEP may also contribute to diminished cardiac output. [47] A useful method of determining when a fall in cardiac output negates the effect of a rise in $Pa_{O2}$ is to calculate the peripheral $O_2$ delivery at different levels of PEEP. [45] [48] One can calculate the peripheral $O_2$ delivery by multiplying the cardiac output by the arterial $O_2$ content as follows:

$O_2$ delivery to periphery = cardiac output × arterial $O_2$ content [11]

One calculates the arterial $O_2$ content by using equation 12 (shown below). The $O_2$ content C (expressed in milliliters of $O_2$ per 100 mL of blood) equals the product:

$C = 0.003 \times PO_2 + 1.34 \times SO_2 \times Hb$ [12]

Here, $SO_2$ is the $O_2$ saturation (available on a blood gas reading) estimated for a given $PO_2$ and Hb is the patient's hemoglobin level (expressed in grams per deciliter).

Measurement of static compliance also has been advocated as a means of determining the optimal level of PEEP. One small study found that the best PEEP from the point of view of $O_2$ delivery to the periphery coincided with the level at which static compliance was highest, usually in the range of 6 to 12 cm $H_2O$. [49] Other researchers have questioned the reproducibility of this association.

**Dual Synchronous Ventilation**

In some patients with severe unilateral lung disease, adequate oxygenation, ventilation, or both, cannot be maintained with safe levels of $Fi_{O2}$ and reasonable pressures. In such patients, PEEP may actually worsen ventilation perfusion mismatch by causing overdistention of the more normal lung and shunting of blood flow to the more diseased lung. A novel approach to ventilating such patients is to use a different ventilator, with different $V_T$ values and pressures, for each lung. Dual-lumen endotracheal tubes are available for this purpose, and some ventilators, such as the Servo 900C, are

specifically designed to be used synchronously with another twin ventilator. Patients with unilateral lung disease due to pneumonia and bronchopleural fistulas have been ventilated successfully with this technique. [50]

## Characteristics of Inspiratory and

## Expiratory Flow

On modern ventilators, many variables of inspiratory and expiratory flow can be altered by the operator. These include inspiratory flow waveform, inspiratory flow rate, inspiratory time, inspiratory-to-expiratory (I:E) ratio, peak inspiratory pressure, and expiratory resistance. These variables, along with rate and $V_T$, are interrelated, so that a change in one affects the others. Which variable is set by the operator and which variable is secondarily determined depends on the ventilator design. For example, in a pressure-cycled ventilator, flow and pressure are set and $V_T$ is determined, whereas in a volume-cycled ventilator, flow and $V_T$ are set and pressure is determined. With a time-cycled ventilator, the I:E ratio is set, whereas with pressure- and volume-cycled ventilators, the I:E ratio is determined. Although changes in the characteristics of inspiratory and expiratory flow tend to result in relatively small changes in the final measures of oxygenation and $CO_2$ elimination, by adjusting these variables appropriately, one can fine-tune the ventilator to optimize the therapy of critically ill patients.

### Inspiratory Flow

The basic flow pattern built into most ventilators is a constant flow (square wave). In many modern ventilators, this basic pattern can be altered by the operator to produce an accelerating (tapered wave) pattern. In most cases, a square wave is chosen as the initial setting, since this leads to lower peak pressures for a given inspiratory time and $V_T$. In some patients with very uneven ventilation of different regions of the lungs, however, use of a tapered inspiratory waveform may result in more even ventilation by allowing more time for the inspired gas to pass through airways with increased resistance to flow. [51]

### Inspiratory Flow Rate

In volume- and pressure-cycled ventilators, the inspiratory flow rate is initially set in the range of 40 to 50 L/min in adults and 8 to 15 L/min in infants. In time-cycled ventilators, one may secondarily determine the inspiratory flow by setting the $V_T$ and inspiratory time. An inspiratory flow rate that is too rapid may lead to dangerously high peak pressures or unequal ventilation of lung units with different time constants, whereas an inspiratory flow rate that is too slow may lead to an undesirably long inspiratory time with inadequate time for exhalation.

### Inspiratory Pause

Some ventilators allow the operator to add a pause to the end of inspiration, during

which time airway pressure is held constant and the patient cannot exhale. Like other maneuvers that prolong the inspiratory phase, an inspiratory pause leads to more even ventilation. [51] The pause may also lead to air trapping. An inspiratory pause is also analogous to PEEP in that by increasing mean airway pressure, it may lead to decreased venous return and decreased cardiac output. An inspiratory pause is usually not initially prescribed, but it may be added when hypoxemia due to uneven ventilation is a problem.

**Inspiratory-to-Expiratory Ratio**

To allow complete exhalation, the expiratory phase of the ventricular cycle should usually be at least twice the length of the inspiratory phase. Higher I:E ratios may lead to air trapping, overdistention, and high peak pressures. It was found in the late 1970s, however, that in infants with hyaline membrane disease, so-called inverse ratio ventilation (IRV) with I:E ratios of 2:1 improved oxygenation and reduced the time infants had to be on high inspired $O_2$ concentrations and PEEP. [52] Inverse I:E ratios as great as 4:1 have also been used in adults with severe hypoxemia due to adult respiratory distress syndrome (ARDS), pneumonia, and cardiogenic pulmonary edema. Inverse ratio ventilation is similar to PEEP in that it improves oxygenation, increases mean airway pressure, reduces $V_D/V_T$ and pulmonary shunt, and may reduce cardiac output. It leads to lower peak pressures than PEEP, however, with less risk of barotrauma. The mechanism by which IRV achieves its beneficial effects is not known for certain, but it is theorized that the long inspiratory time may lead to more even ventilation, and the short expiration time may prevent collapse of diseased alveoli.

**Peak Pressure**

With pressure-cycled ventilators, peak pressure is a set variable and determines $V_T$. Starting pressures of 20 to 25 cm $H_2 O$ are commonly used in adults with normal compliance, although pressures 40 cm $H_2 O$ are usually required in patients with a pathologic pulmonary condition.

With time- and volume-cycled ventilators, peak pressure is determined mainly by $V_T$. Typical peak pressures for patients with respiratory failure are in the range of 40 to 50 cm $H_2 O$. Peak pressures >60 cm $H_2 O$ are not uncommon but are associated with a higher incidence of barotrauma. In exceptional cases, peak pressures of 100 cm $H_2 O$ are required. Modern volume- and time-cycled ventilators have

adjustable peak pressure limits such that when the airway pressure exceeds the set limit, inspiration is terminated. The limit is usually set at 10 cm $H_2 O$ above the peak pressure that is observed when the patient is initially placed on the ventilator. If the peak pressure alarm sounds later, it is a sign that the patient's compliance has dropped or that resistance has increased, and the cause must be sought. Typical causes of acute increases in peak pressure include attempts by the patient to override, or "buck," the ventilator, development of pneumothorax, migration of the tip of the endotracheal tube into the right main stem bronchus, kinking of the tube, or plugging of the tube or a major airway.

**Expiratory Retard**

Many ventilators have an adjustable expiratory resistance, or retard. The development of such a mechanism was inspired by the observation of COPD patients who breathe through pursed lips, apparently in an effort to increase their own expiratory resistance. Theoretically, this resistance to expiration may prevent the premature collapse of small airways and may paradoxically lead to more complete exhalation. Whether this is actually the reason for pursed-lip breathing and whether expiratory retard is a useful setting on a ventilator remain controversial.

**Sighs**

In the early 1960s, it was shown that patients who were being mechanically ventilated during anesthesia showed a progressive decline in compliance and widening of their A-a$DO_2$ . [56] These changes were thought to be caused by atelectasis and were reversed by intermittent deep breaths. Based on this work, "sigh" functions have been built into mechanical ventilators, allowing the operator to introduce a breath 1.5 to 2.0 times the usual $V_T$ at regular intervals. A problem with the original study that demonstrated the benefit of "sighs," however, was that patients were ventilated with low $V_T$ levels. With the $V_T$ levels that are used today, which are in the range of 10 to 15 mL/kg, it has not been demonstrated that progressive atelectasis occurs. The optimal rate and volume of sighs are unknown, nor is it known whether sighs are beneficial. Indeed, it has been argued that incorporation of a sigh function into a ventilator adds only needless extra expense. [57]

**Permissive Hypercapnia**

The concept of permissive hypercapnia represents an alternate approach to conventional mechanical ventilation concepts. While $V_T$ values of 10 to 15 mL/kg (regardless of the inspiratory pressures required) are usually recommended as initial settings, high peak pressures have been shown to produce lung injury in numerous settings (e.g., ARDS, asthma). The avoidance of "volutrauma" by pressure or volume limitation theoretically prevents ventilation-induced lung injury. With permissive hypercapnia a lower $V_T$ of 5 to 8 mL/kg is used to prevent excessive alveolar distention, but the tradeoff is a rise in $Pa_{CO_2}$ and a decrease in serum pH. Both hypercapnia and acidemia are apparently well tolerated in critically ill patients. Although previously believed to be detrimental, good outcomes have been described despite previously "unacceptably high" $Pa_{CO_2}$ . [58] [59] Some authors advocate adjusting the serum pH with sodium bicarbonate whereas others also allow a mild "permissive acidemia." [59]

Permissive hypercapnia allows arterial $p_{CO_2}$ to rise above 50 to 60 mm Hg. Using low $V_T$ values and peak inspiratory pressures <40 cm $H_2$ O, Hickling and colleagues  report significant decreases in mortality rates in patients with ARDS whose mean $Pa_{CO_2}$ was in the range of 62 to 66 mm Hg and mean serum pH was 7.23 (range, 6.8 to 7.45). Neuromuscular blockade is usually required to achieve pressure-volume limitation. Permissive hypercapnia is easy to perform and appears free of complications, but it is contraindicated in those with intracranial hypertension in which a high $p_{CO_2}$ may further

elevate intracranial pressure.

## Humidification

Inspired air is normally humidified and warmed in the oropharynx and the nasopharynx before reaching the lower airway. In an intubated patient, inspired air bypasses the nasopharynx and the oropharynx and is injected directly into the trachea. To prevent drying of the mucosa of the lower airways, all modern ventilators are equipped with systems for humidifying and warming inspired air. The setup of these systems varies from ventilator to ventilator and is described in the operating manuals supplied by the manufacturers. A commonly overlooked setting, however, is the temperature of the inspired air. Normally, the air temperature should be 35 °C at the point at which the gas enters the endotracheal tube. One should remember that in patients who are hypothermic, heating the inspired air is an adjunctive means of core rewarming. [9] Likewise, cooling the inspired air will lower the body temperature in febrile patients.

## Medication Nebulizers

Most modern ventilators have in-line medication nebulizers for the administration of bronchodilator drugs. The dosages are the same as for medication nebulizers for patients who are breathing spontaneously. Special mention should be made of ribavirin, a synthetic nucleoside analogue approved for aerosol treatments of infants and young children with severe respiratory syncytial virus infections. Ribavirin has been reported to cause malfunction of ventilators because of precipitation of the drug on the valves and in the ventilator tubing. Special filters must be used when this drug is delivered via the nebulizer on a mechanical ventilator

# VENTILATOR USE

## Specific Situations Requiring Ventilation

### Acute Respiratory Distress Syndrome

An acceptable arterial oxygen saturation (i.e., 90%) should be targeted in patients with ARDS, but the $Fi_{O2}$ should be minimized (0.6) whenever possible to decrease $O_2$ toxicity. A plateau pressure of 35 cm $H_2O$ is of concern, and it may be desirable to decrease $V_T$ to as low as 5 mL/kg to alleviate excessive pressures. Such patients may be candidates for permissive hypercapnia. While PEEP is quite useful in ARDS because it permits the reduction of $Fi_{O2}$ to less toxic levels, the level of PEEP should be applied judiciously to avoid high peak airway pressure barotrauma. When oxygenation is inadequate, sedation, paralysis, and position change are parameters that should be carefully reviewed. Because a

depression in cardiac output commonly occurs in hypovolemic patients placed on PEEP, volume repletion may be required. Because effects on cardiac output are complex and quite unpredictable, most patients with ARDS require pulmonary artery

catheter placement to assess hemodynamic parameters.

**Severe Acute Asthma**

Mechanical ventilation of the severe asthmatic is both difficult and hazardous. A major concern is ventilator-induced hyperinflation due to high plateau pressures (35 cm $H_2O$) and high peak airway pressure (PAP) (50 cm $H_2O$). It is therefore desirable to minimize plateau pressures and PAP in patients with asthma. Increasing the lumen of the tracheal tube may help to minimize peak airway pressures, and other approaches specific to mechanical ventilation in acute asthma are outlined in Table 7-4 (Table Not Available) . The clinician should aim to decrease minute ventilation and increase expiratory time. In many instances, it is permissible to accept an elevated $Pa_{CO_2}$ as long as pH can be maintained in an acceptable range. Paralysis and/or sedation are usually necessary to effectively achieve ventilatory goals in severe asthma.

## Choosing a Ventilator

With the large variety of commercial ventilators available today, choosing the best ventilator for one's hospital or hospital department can be a difficult decision. One factor in deciding which ventilator is best is the setting in which the ventilator will be used. In an emergency department in which mechanical ventilation is done infrequently and for short periods, a relatively simple ventilator that is easy to set up and to operate may be preferable to a more complex machine that offers more controls and monitors. Although some ventilators, such as the Siemens Servo 900C, can be used for both infants and adults, ventilators designed specifically for infants are usually preferred in pediatric and neonatal intensive care units. Safety and reliability are major concerns in choosing a ventilator. Fortunately, most modern ventilators have both features. Cost is another factor to be considered. The improvements in ventilator technology since the mid-1980s have not come cheaply. Many ventilators today cost more than $20,000. Table 7-5 (Table Not Available) lists some features that are most desirable in a ventilator and some other features that may add significantly to the cost but may not be as necessary.

## Ventilator Setup

The actual setup of a ventilator is usually done by a respiratory therapist under the direction of a physician. In some cases, a respiratory therapist or other knowledgeable nonphysician may not be available immediately, and the physician may need to do the actual ventilator setup. Unfortunately, it is not practical to describe in this chapter the step-by-step setup of every ventilator currently in use. Instead, setup of a state-of-the-art infant ventilator, the Infant Star, and the versatile Siemens Servo 900C, which can be used in both infants and adults, is described. The descriptions of ventilator setup that follow are not intended to provide everything one needs to know to operate either of these ventilators safely. Rather, these descriptions are intended to

serve as examples of the typical steps in the setup of modern ventilators. For complete instructions regarding the setup of these or other ventilators, the operator should consult the operating manuals supplied by the manufacturers. Copies of these manuals should

be available in any departments in which the ventilators are in use.

If at any point during ventilator setup the patient appears to have inadequate ventilation, the patient should be taken off the ventilator and should be bag ventilated. Troubleshooting of ventilator setup should *not* occur while the patient is dependent on the ventilator.

**Setup of the Infant Star**

The Infant Star is a time-cycled ventilator, designed especially for mechanical ventilation of infants and children. The actual ventilator is shown in Figure 7-4 (Figure Not Available) and the control and display panels are depicted schematically in Figure 7-5 (Figure Not Available) . The ventilator is controlled by 2 microprocessors that allow precise tailoring of ventilator settings and provide alarms and monitors not found on most other pediatric ventilators. The ventilator may be connected by a standard computer cable to an IBM-compatible personal computer for making printouts of monitored parameters and trends. The ventilator software can be updated, and high-frequency ventilation is an enhancement that is currently available.

Two modes are basically available on the Infant Star--CPAP and IMV. With either mode, continuous or demand flow is possible. Demand flow conserves the hospital $O_2$ supply with minimal, if any, increase in the work of breathing as a result of the rapid response time of the microprocessor-controlled inspiratory flow valves. Setup in the IMV mode with demand flow is described here.

**Step-by-step setup.**

1. Air, $O_2$ , and electrical power hookups at the back of the ventilator are connected to hospital sources.
2. Inspiratory and expiratory arms of patient breathing tubes are connected to the ports labeled TO PATIENT and FROM PATIENT on the compressor front panel. (Note that a separate humidifier must be used.) Special 1/8-inch tubing is connected from the patient Y to the PROXIMAL AIRWAY PRESSURE port.
3. The power switch at the back of the ventilator is turned on, and the operator checks that all digital displays are illuminated and bright, that an audible alarm sounds momentarily, and that all light-emitting diode indicators are illuminated, except POWER LOSS, VENT INOP, and INTERNAL BATTERY.
4. Ventilator settings are made by turning the appropriate knobs on the control panel and compressor. Although the appropriate settings will be determined by the clinical situation, typical settings for an infant would be FLOW RATE 20 L/min, RATE 30 breaths/min, PEAK INSPIRATORY PRESSURE 50 cm $H_2$ O, INSPIRATORY TIME 1 second, and LOW INSPIRATORY PRESSURE 10 cm $H_2$ O.
5. Connect the patient Y to a test lung to check inflation and deflation at the appropriate rate.
6. Disconnect the patient Y from the test lung and check that the LOW INSPIRATORY PRESSURE ALARM is activated. Obstruct the tube at the patient Y to be sure that the OBSTRUCTED TUBE alarm is activated. Partially obstruct

the patient Y and rotate the pop-off valve on the front of the compressor until gas is felt to escape from the valve at a pressure of about 60 cm $H_2O$ as read off the analogue pressure gauge. Reconnect the patient Y to the test lung and push the ALARM SILENCE and VISUAL RESET buttons.

7.  Set the desired $Fi_{O2}$ on the front of the ventilator compressor.
8.  Connect the ventilator to the patient and observe for rise and fall of the patient's chest and appropriate pressures, I:E ratio, and expiration time. Readjust the PEAK INSPIRATORY PRESSURE to 5 to 10 cm $H_2O$ above the observed peak inspiratory pressure and the LOW INSPIRATORY PRESSURE to 5 to 10 cm $H_2O$ below the observed peak inspiratory pressure. Readjust the pop-off valve to 13 cm $H_2O$ above the set peak inspiratory pressure limit.

**Alarms and monitors on the Infant Star.**

The Infant Star has 9 alarm systems plus an indicator to signal that the ventilator is running on its internal battery if the outside power source fails. All alarms are both audible and visual, except for a portion of the OBSTRUCTED TUBE alarm. Alarm lights are located on the lower right-hand corner of the ventilator control panel (see Fig. 7-5) (Figure Not Available) . Audible alarms can be silenced for 60 seconds by pushing the ALARM SILENCE button, with the exception of the VENTILATOR INOPERATIVE and POWER LOSS alarms, which cannot be silenced.

**LOW INSPIRATORY PRESSURE.**

This alarm is activated when the peak inspiratory pressure of a given breath does not reach the set alarm limit. By setting the alarm limit within 5 to 10 cm $H_2O$ of the observed peak inspiratory pressure, the alarm will detect any significant leaks in the inspiratory circuit. Setting the alarm limit closer to the observed peak inspiratory pressure will lead to frequent false alarms.

**LOW PEEP/CPAP.**

The microprocessor automatically sets the low PEEP and CPAP limits to 2 to 5 cm $H_2O$ below the set PEEP and CPAP levels. The alarm is activated if PEEP or CPAP falls below the automatic limits.

**AIRWAY LEAK.**

This alarm is activated when demand flow exceeds background flow for 4 seconds. It supplements the low inspiratory pressure and low PEEP/CPAP alarms.

**OBSTRUCTED TUBE.**

This alarm is activated when peak inspiratory pressure or PEEP or CPAP significantly exceeds the set levels, usually indicating an obstructed breathing tube. The alarm is actually sensitive to 5 different specific violations, and the exact violation is displayed in

coded form in the window above the alarm lights. Explanations of the 5 different codes and the most likely malfunction associated with each alarm code are described in detail in the operating instructions provided with the ventilator.

**INSUFFICIENT EXPIRATORY TIME.**

This alarm is activated when exhalation time for mandatory breaths is <0.3 seconds.

**LOW O$_2$ PRESSURE and LOW AIR PRESSURE.**

These alarms are activated when the pressure of gases into the ventilator drops below 45 psi. Below this pressure, the blender may be affected, and inaccurate F$_{IO2}$ settings may result.

**POWER LOSS and INTERNAL BATTERY.**

The internal battery light comes on whenever outside power fails and the ventilator is running on its internal battery. Approximately 5-10 minutes before the internal battery is exhausted, the internal battery and power loss lights alternately flash. When fully charged, the internal battery provides up to 30 minutes of operation.

**VENTILATOR INOPERATIVE.**

This alarm signals a major malfunction, which makes the ventilator unsafe. When this alarm activates, the ventilator shuts down and all valves open, allowing the patient to breathe ambient air. Possible causes of ventilator malfunction are detailed in the operating instructions.

Monitors on the Infant Star include an analogue proximal airway pressure manometer; digital displays for PEEP and CPAP, mean airway pressure, and peak inspiratory pressure; and a digital display with a 3-way switch that may be turned to read PEEP/CPAP, I:E RATIO, or EXPIRATION TIME. The monitors are for the most part self-explanatory. The MEAN AIRWAY PRESSURE monitor is a particularly useful feature of the Infant Star, because mean airway pressure has a direct bearing on the risk of barotrauma and on oxygenation and cardiac output.

**Setup of the Siemens Servo 900C**

The Siemens Servo 900C is a compact yet versatile and dependable modern ventilator, which operates almost silently. With its many accessories, it can be used as a ventilator for infants, children, or adults; as an anesthesia machine; or as a diagnostic instrument. Although it is basically a time-cycled ventilator, volume and pressure limits can be set to make it function like either a volume-cycled or a pressure-controlled machine.

The modes available on the Siemens Servo 900C deserve special mention, because they are somewhat different from those available on most other ventilators. In the

VOLUME CONTROL mode, the ventilator functions much like a typical volume-cycled ventilator, except that the operator sets the desired minute volume rather than the desired $V_T$. The

operator then sets the desired respiratory rate and I:E ratio, and through its internal electronic circuitry, the ventilator determines the inspiratory flow necessary to deliver the set minute volume. A VOLUME CONTROL PLUS SIGH mode, in which every 100th breath is delivered with double the basic $V_T$, is also available. By adjusting the TRIGGER SENSITIVITY appropriately, the VOLUME CONTROL mode becomes analogous to "assist control" in a volume-cycled ventilator. In the PRESSURE CONTROL mode, the ventilator delivers a constant pressure, with a decelerating flow pattern, during a set inspiratory time. The inspiratory pressure, respiratory rate, and inspiratory time determine the $V_T$ received by the patient. PRESSURE SUPPORT is a unique mode in which the patient must initiate all breaths independently, but assistance is provided by positive pressure from the ventilator each time a sufficient inspiratory effort is made. The $V_T$ of each breath depends in part on the set inspiratory pressure and in part on the amount of effort made by the patient. This mode is suggested by the manufacturer for weaning patients from anesthesia or from mechanical ventilation.

The SIMV mode is the same as that in a volume-cycled ventilator except the minute volume rather than $V_T$ is set. SIMV PLUS PRESSURE SUPPORT combines these 2 modes, providing the patient with a set minute volume at a set rate but allowing the patient to breathe spontaneously between machine breaths, with the ventilator applying positive pressure during the spontaneous inhalations. The CPAP mode is the same as that in a volume ventilator. A MANUAL mode is also available for providing manual ventilation during the administration of anesthesia or while a patient is being suctioned.

The external appearance of the Servo 900C is shown in Figure 7-6 (Figure Not Available) . The assembly of the ventilator to this point as well as the attachment of the humidifier, the $O_2$ -air mixer, and the patient tubing are discussed in detail in the manufacturer's instruction manual. The power supply cord (which must be plugged into a standard 110-volt AC outlet) and the on/off switch are located at the rear of the electronic unit. The further setup of the ventilator is illustrated in Figure 7-7 (Figure Not Available) and is discussed here. Setup is described for the ASSIST CONTROL mode, because this is the mode that is most appropriate for initial ventilation of most adult patients in the emergency department or the critical care unit. The setup in other modes varies slightly and is covered in the manufacturer's manual.

**Step-by-step setup.**

1. The WORKING PRESSURE adjustment on the pneumatic unit, which is mounted above the electronic unit, determines the maximum pressure that the ventilator will deliver and provides a secondary safeguard against the inadvertent exposure of the patient to dangerously high pressures. (The primary safeguard is the UPPER PRESSURE LIMIT setting on the ventilator control panel, described in step 12.) The recommended working pressure for most adult patients is 60 cm $H_2$ O. Higher pressures, up to 120 cm $H_2$ O, may be required in rare cases.
2. The mode selector switch may be turned to either VOLUME CONTROL or

VOLUME CONTROL PLUS SIGH. As discussed previously, the sigh function is not recommended.

3. The PRESET INSPIRATORY MINUTE VOLUME control determines the minute volume that the ventilator will deliver if the patient initiates no breaths independently. As discussed previously, not all of the volume that is delivered by the ventilator actually reaches the patient, beause

    some is lost to compression within the humidifier and the patient tubing. The difference between the preset inspiratory minute volume and the minute volume that the patient actually receives is on the order of 400 to 600 mL/min for a typical adult patient. A method of calculating the exact difference is given in the operating manual.

4. Either a square wave or an accelerating inspiratory flow pattern may be selected. In most cases, a square wave is the appropriate initial setting (see discussion in the section on inspiratory flow).

5. The BREATHS/MINUTE knob determines the minimum number of breaths that the patient will receive. One determines the $V_T$ of each breath by dividing the preset inspiratory minute volume by the number of breaths per minute. The patient may trigger the ventilator at a faster rate than the breaths per minute setting, in which case the patient will receive more than the preset inspiratory minute volume. The $V_T$ of the ventilator breaths will not change, however.

6. 6 and 7. The INSPIRATORY TIME PERCENT setting determines the fraction of each respiratory cycle that is spent in inspiration. The PAUSE TIME PERCENT setting may be used to provide a pause at the end of inspiration that is up to 20% of the respiratory cycle. In combination, the inspiratory time percent and pause time percent settings determine the I:E ratio, which may be set anywhere from 1:4 to 4:1. The recommended initial setting is an inspiratory time of 33% with no pause, resulting in an I:E ratio of 1:2. (See the sections on inspiratory pause and I:E ratio for a discussion of the use of an inspiratory pause and different I:E ratios.)

7. The inspired $O_2$ concentration is set by a control on the air-$O_2$ mixer attached to the right side of the ventilator.

8. The UPPER and LOWER ALARM LIMIT controls should be set approximately 6% above and below the desired $O_2$ concentration. When the $F_{IO_2}$ varies outside the set limits, as detected by the internal $O_2$ analyzer on the ventilator, visible and audible alarms are activated.

9. The PARAMETER SELECTOR knob determines which parameter is displayed in the digital readout window on the control panel above the knob. The available parameters include breathing rate (sum of spontaneous and mechanical), actual $FIO_2$ , inspiratory $V_T$, expiratory $V_T$, expired minute volume, peak pressure, pause pressure, and mean airway pressure.

10. If PEEP is required, one sets the desired level by turning the PEEP knob.

11. The UPPER PRESSURE LIMIT knob allows the operator to set a ceiling for airway pressure above which inspiration is terminated, and visible and audible alarms are activated. The limit should be set at approximately 50 cm $H_2O$ initially and should be readjusted with the patient on the ventilator to 10 to 15 cm $H_2O$ above the observed peak pressure. If the upper pressure limit is set above the working pressure (see step 1), inspiration will end when the working pressure is reached, but no alarms will be activated.

12. The TRIGGER SENSITIVITY control determines how much inspiratory effort the patient must make to trigger an assisted ventilator breath. The sensitivity is usually set so that an inspiratory effort of -1 to -3 cm $H_2O$ is required.
13. The EXPIRED MINUTE VOLUME meter at the top left corner of the ventilator control panel has dual scales: from 0 to 40 L/min for adults and from 0 to 4 L/min for children. The proper scale is selected with the INFANTS/ADULTS switch at the lower left corner of the control panel. This switch also sets the scale for the UPPER and LOWER ALARM LIMIT controls (see step 16).
14. The ventilator is now connected to the patient. In addition to observing the clinical response of the patient, one should use the PARAMETER SELECTOR control and EXPIRED MINUTE VOLUME and AIRWAY PRESSURE meters to be sure that the rate, $V_T$, minute volume, $Fi_{O2}$, and airway pressures are in the desired range.
15. After the patient has been on the ventilator for a few minutes and it has been determined that the patient is receiving an appropriate minute volume, the UPPER and LOWER ALARM LIMIT controls should be set approximately 20% above and below the desired minute volume. When the expired minute volume deviates from this range, visible and audible alarms are activated.

The alarms that are included for patient safety are depicted in Figure 7-8 (Figure Not Available) . Alarms are given in the form of audible signals as well as flashing red lights. One can switch off most of the audible alarms for 2 minutes by depressing the ALARM SILENCE button on the control panel.

In addition to the features discussed previously, available options on the Servo 900C include a $CO_2$ monitor, which analyzes end-tidal $CO_2$ and has alarms for levels of $CO_2$ above or below set limits; a lung mechanics calculator, which calculates airway resistance and compliance; and a paper strip recorder, which can print pressure-flow curves or graphically present the digital displays from the ventilator control panel.

**Sedation and Paralysis**

Whereas many patients adapt readily to mechanical ventilation and synchronize their own breathing with the ventilator breaths, other patients "fight the machine." By coughing, bucking, and breathing out of phase with the ventilator, they generate high peak airway pressures and increase their $O_2$ consumption and $CO_2$ production. When their airway pressures exceed the peak pressure limits, they receive less than the prescribed $V_T$, and hypoventilation results. In such cases, *a complication or a mechanical problem must first be ruled out*. One should check the inspired $O_2$ concentration with an $O_2$ analyzer to be sure that the set $Fi_{O2}$ is really being delivered. While the patient is being "bagged" by hand, increased resistance to inflow of air, suggesting a plugged or kinked endotracheal tube, can be sensed. Malposition of the endotracheal tube and pneumothorax should be ruled out by auscultation and a chest film. The patient should be suctioned to remove any large airway obstruction due to mucus, blood, or other debris. Other causes for agitation, such as hypotension or pain, should be considered. If coherent, the patient should be reassured.

When all of these measures have been taken, no complication or malfunction has been

found, and the patient continues to fight the ventilator, sedation should be considered. Diazepam is a useful drug in this setting. Diazepam acts rapidly and provides excellent relaxation, sedation, and amnesia. The usual starting dose in adults is 2.5 to 5.0 mg IV, given at a rate of 2.5 mg/min. Because the main side effect is respiratory depression, much larger doses, up to 1 mg/kg, can be given in a mechanically ventilated patient, although some cardiac depression occurs at very high doses (>3 mg/kg).

An alternative to diazepam is morphine sulfate. Morphine is usually given in 2- to 4-mg increments IV and titrated to effect. As with diazepam, the main side effect of morphine is respiratory depression, which is not a problem in the mechanically ventilated patient with a secure airway. The drug also causes a small drop in blood pressure, probably a result of peripheral vasodilation rather than a direct cardiac depressant effect. [64] Morphine is also known to cause histamine release, which could theoretically lead to increased bronchospasm. [64] Whether this effect is of clinical significance is unknown. Advantages of morphine over diazepam are that it is a potent analgesic and its effect is readily reversible with naloxone.

When sedation and analgesia are ineffective in preventing the patient from fighting the ventilator, a paralyzing drug may be used. Pancuronium bromide is the drug of choice for inducing paralysis in ventilator patients. Pancuronium is a nondepolarizing blocker of neuromuscular transmission. The main side effects of the drug are a mild increase in pulse and blood pressure, although it has also been reported to cause severe hypertension, ventricular dysrhythmias, and anaphylactic reactions on rare occasions (also see Chapter 3) .

Pancuronium is preferred over *d*-tubocurarine, which commonly causes hypotension, and the depolarizing agent succinylcholine, which is short acting and causes fasciculations and cholinergic side effects. [65] The dose of pancuronium is 0.02 to 0.06 mg/kg IV. Paralysis occurs within 1 to 3 minutes and lasts 1 to 2 hours, after which time repeated doses may be given. Paralysis induced by pancuronium can be reversed by neostigmine, 0.06 to 0.08 mg/kg IV up to a total of 2.5 mg. Physostigmine should *not* be used for reversal, because it crosses the blood-brain barrier and may induce seizures. Atropine, 0.01 to 0.02 mg/kg up to a total of 1 mg, should be given in the same syringe to block the cholinergic side effects of neostigmine. Paralysis with pancuronium has been reported to be particularly effective in asthmatics. [66] This agent is also used frequently in neonates with hyaline membrane disease, in whom it has been shown to increase compliance and $Pa_{O_2}$ . [67]

It is important to remember that although a patient who is paralyzed with pancuronium or other newer agents (see Chapter 3) may appear asleep and calm, the drug has no sedative or analgesic properties. A paralyzed patient must be given liberal doses of sedatives and analgesics at regular intervals. Hospital personnel should treat the patient as if fully awake, talking to the patient in a reassuring manner and avoiding bedside discussion of the case. Finally, the patient must be continually observed and ventilator function and alarms must be checked frequently, because the patient will be entirely unable to breathe independently should the ventilator fail.

# COMPLICATIONS OF MECHANICAL VENTILATION

In a prospective study of 354 episodes of mechanical ventilation at the University of Colorado from 1972 to 1973, there were 400 complications. [68] Although most were minor, some were associated with increased patient mortality. It is probably not surprising that there is a high incidence of complications with mechanical ventilation, because it is an invasive form of therapy using complex equipment in critically ill patients for prolonged periods. To some extent, however, the complications are preventable. Others that are not preventable at present should at least be anticipated so that when they occur, they can be recognized and dealt with promptly.

The potential complications of ventilator therapy are listed in Table 7-6 . Complications related to intubation and the presence of an endotracheal tube are dealt with in more detail elsewhere in this text but deserve mention here. Intubation

| **TABLE 7-6** -- Potential Complications of Mechanical Ventilation |
| --- |
| Complications related to endotracheal or tracheostomy tube |
| Tube malfunction (leaking cuff, kinked tube, obstruction caused by herniation of balloon over end of tube) |
| Pressure phenomena (nasal and tongue necrosis due to pressure from the tube, laryngeal ulceration and polyps, tracheal stenosis and malacia, fistulas into esophagus and innominate artery) |
| Complications resulting from machine malfunction and operator error |
| Failure of ventilator to deliver set tidal volume, rate, $Fi_{O_2}$ , etc |
| Inappropriate settings ordered |

| |
|---|
| Settings not fixed as ordered (commonly includes wrong rate, $V_T$, and $F_{IO_2}$ ; assist control sensitivity too high or too low) |
| Alarm failure |
| Alarm turned off and left off |
| Inadequate humidification |
| Overheating or underheating of inspired air |
| Patient accidentally disconnected from ventilator |
| Direct effects of positive-pressure ventilation |
| Barotrauma (pneumothorax, tension pneumothorax, pulmonary interstitial emphysema, subcutaneous emphysema, pneumomediastinum, pneumoperitoneum, air embolism) |
| Decreased venous return and cardiac output |
| Other complications |
| Ventilator-associated pneumonia |
| Oxygen toxicity and retrolental fibroplasia |

of the right main stem bronchus was one of the most common complications in the University of Colorado study and was associated with other problems, including pneumothorax and atelectasis, as well as with decreased survival. Complications related to pressure from the endotracheal tube cuff have declined since the introduction of high-volume, low-pressure cuffs, which require <25 mm Hg to produce a seal. Whereas it was recommended in the older literature that a tracheostomy be performed in patients requiring mechanical ventilation for >1 to 2 weeks, more recent studies have reported fewer complications with soft cuff endotracheal tubes in place for up to 3 weeks than with tracheostomies. [69] There has been one report of orotracheal intubation for 2 months without complications. [70] The safety of orotracheal vs. nasotracheal intubation has not been studied systematically. In general, nasotracheal intubation is better tolerated by the patient, is more secure, and allows better mouth care. On the other hand, it leads to a higher incidence of sinusitis and necrosis of the nasal mucosa and cartilage.

The incidence of complications related to ventilator malfunction has declined as ventilators have become more reliable, but operator errors remain a significant problem. One of the most common yet potentially serious errors is to turn off a ventilator alarm and to forget to turn it back on. This happens most frequently when the patient is disconnected briefly from the ventilator for suctioning. With many older ventilators, such as the Puritan-Bennett MA-1, one can permanently silence the alarm that signals when the patient has failed to receive a full $V_T$ by turning off a single switch. If this alarm is not turned back on after the patient has been suctioned, the patient, by turning the head, may later cause the ventilator tubing to become disconnected from the endotracheal tube. The next indication that something is wrong may be the development of a ventricular dysrhythmia on the cardiac monitor. To prevent this occurrence, many modern ventilators have been designed with alarms that can be turned off by the operator only for 1 to 2 minutes before they reactivate themselves.

Barotrauma remains a relatively common complication of ventilator therapy. Pneumothorax is the most common form of barotrauma and may be preceded or accompanied by pulmonary interstitial emphysema, pneumomediastinum, subcutaneous emphysema, and pneumoperitoneum. In patients receiving ventilatory assistance, pneumothorax is more often than not of the tension type. The reported incidence of pneumothorax in mechanically ventilated patients varies in the literature from 0.5 to 14%. The highest incidence of barotrauma occurs with the use of levels of PEEP >24 cm $H_2O$, [74] whereas levels of PEEP of 5 cm $H_2O$ and below do not seem to be associated with increased risk. [73] The incidence of pneumothorax is also particularly high in patients with asthma. [11]

It has been reported that the incidence of barotrauma is lower with pressure-cycled than with volume-cycled ventilators. [72] This is not surprising when it is considered that higher pressures are commonly used with volume-cycled ventilators. Judicious use of sedation

and paralysis may help reduce pressures and thereby lower the risk of barotrauma. It has been argued that it is safer to allow patients with asthma to remain hypercapnic for periods of hours to days rather than to use peak pressures above 50 cm $H_2O$. [75]

In patients who are on high levels of PEEP or who require high peak pressures, the development of barotrauma should be anticipated. A pneumothorax should be suspected whenever there is a sudden deterioration in compliance and blood gas values. Pneumothorax should be confirmed by auscultation, palpation of the position of the trachea, and, if time permits, a chest film. In the patient whose condition is deteriorating rapidly, needle thoracostomy is both diagnostic and therapeutic (see Chapter 8) , but it should be followed promptly by tube thoracostomy (see Chapter 9) .

Pneumoperitoneum is a form of barotrauma that deserves special mention. The incidence of pneumoperitoneum and pneumoretroperitoneum has been reported to be as high as 4% in patients on PEEP. [76] Pneumoperitoneum is typically preceded by pulmonary interstitial emphysema, subcutaneous emphysema, and pneumomediastinum and is usually, but not always, accompanied by pneumothorax. Patients with ventilator-induced pneumoperitoneum have been subjected to needless laparotomies in a search for the cause of abdominal free air. [77] Another unusual form of barotrauma is fatal arterial and venous air embolism, which has been reported in association with tension pneumothorax in premature infants receiving mechanical ventilation. [78]

Another potential problem that is a direct effect of positive-pressure ventilation is diminished cardiac output. As discussed in the section on PEEP, a clinically significant fall in cardiac output usually occurs at levels of PEEP of 12 to 15 cm $H_2O$. A drop in cardiac output has also been shown to be a result of positive-pressure ventilation without PEEP. [17] The fall in cardiac output seen with mechanical ventilation is thought to be caused by decreased venous return as a result of increased intrathoracic pressure. This effect is greatest when mean airway pressures are highest, as in controlled ventilation with PEEP, and is negligible when low mean airway pressures are used, as in the IMV mode with a low

mechanical breathing frequency. [13] It has been shown in the case of PEEP that the fall in cardiac output is at least partly reversible with blood volume expansion. [46] The influence of positive-pressure ventilation on venous return also depends on the extent to which airway pressure is transmitted to the pleural space. When lung compliance is high and chest wall compliance is low, as in COPD, much of the airway pressure is transmitted to the pleural space, and venous return is impaired more than in conditions such as ARDS, in which lung compliance is low.

It should not be assumed that the effect of positive-pressure ventilation on cardiac function is always detrimental. It has been shown that patients with respiratory distress may generate highly negative intrathoracic pressures during spontaneous breathing and that this negative pressure acts as increased afterload on the heart. [79] Although venous return into the thorax is enhanced by negative intrathoracic pressure, ejection of blood out of the thorax is impeded, and the more negative the intrathoracic pressure, the harder the left ventricle must pump to reach a given systemic arterial pressure. [80]

Mechanical ventilation substitutes positive for negative intrathoracic pressure, thereby decreasing afterload on the left side of the heart. In most cases, the effect of positive-pressure ventilation in decreasing venous return to the heart outweighs its effect in decreasing afterload, and decreased cardiac output results. In patients breathing spontaneously on PEEP as compared with those breathing spontaneously without PEEP, however, an increased cardiac output has been demonstrated. [81]

Pneumonia is one of the more common complications of intubation and mechanical ventilation. In a review of infections related to medical devices, it was found that ventilator-associated pneumonia was second in frequency only to catheter-related cystitis, and it was estimated that 75,000 ventilator patients a year acquire nosocomial pneumonia, with a fatality rate of 40%. [82] In another large-scale retrospective study, the incidence of nosocomial pneumonia was 0.3% in patients not on ventilators, 1.3% in patients ventilated by endotracheal tube, and a surprising 66% in patients ventilated by tracheostomy. [83] No pneumonias developed in patients ventilated <24 hours, whereas there was an abrupt rise in risk for patients ventilated >5 days.

Most cases of ventilator-associated pneumonia resulted from enteric gram-negative organisms. Ventilator-associated pneumonias may be preventable in part by strict adherence to sterile technique during suctioning and by avoidance of prolonged ventilation or tracheostomy whenever possible. Ventilator humidification systems are a potential source of bacterial contamination, and it is the policy at many hospitals to change the ventilator tubing and humidification system every 24 hours. With the cascade humidifiers used on most modern ventilators, however, there is probably little risk of introducing bacteria into the inspired gas mixture, and it has been shown that the system need not be changed more often than every 48 hours. [84]

Oxygen toxicity was discussed as a potential complication of mechanical ventilation in the section on inspired $O_2$ concentration. Although the exact dose-time relationship of $O_2$ toxicity has not been worked out, it should be assumed that an $F_{IO_2}$ 0.50 has the potential to produce toxic effects. In many cases, $O_2$ toxicity can be avoided by using measures such as PEEP, which improves the A-a$_{DO_2}$ and allows use of lower inspired $O_2$ concentrations.

A final condition that should be included as a potential complication of mechanical ventilation is bronchopulmonary dysplasia. Bronchopulmonary dysplasia is a form of chronic lung disease that occurs in infants who have been mechanically ventilated for severe hyaline membrane disease. It is characterized radiographically by cystic enlargement of the airways with intermingled dense, strand-like infiltrates. The incidence of bronchopulmonary dysplasia is 6 to 11% in survivors of hyaline membrane disease. [33] It is not known whether bronchopulmonary dysplasia results from high inspired $O_2$ concentrations, high airway pressures, or the evolution of hyaline membrane disease itself. One small study has suggested that intramuscular administration of vitamin E may modify the development of bronchopulmonary dysplasia. [85] Until more is known about the actual cause of this condition, however, it cannot be considered preventable.

## HIGH-FREQUENCY VENTILATION

More than 800 articles have been published on high-frequency ventilation (HFV) since the technique was introduced in Sweden in 1967, and it has been the subject of several recent reviews.  High-frequency ventilation differs radically from the traditional approach of using $V_T$ values and frequencies in the physiologic range. Instead, $V_T$ values of a few milliliters per kilogram are used at rates from 60 to 3000 breaths/min. The chest does not rise and fall in patients on HFV unless they breathe spontaneously around the ventilator. One might expect that only the dead space gas would be exchanged and that no alveolar ventilation would occur at all. In fact, however, it has been found that adequate ventilation and $O_2$ exchange do occur by mechanisms that are still not completely understood but that include facilitated diffusion of gases along the vibrating column of air.

High-frequency ventilation has found practical application in laryngeal surgery, in which it allows the surgeon a clear view of a motionless larynx. It has also been used successfully to ventilate patients with large bronchopleural fistulas in whom conventional mechanical ventilation has failed because of massive air leaks. High-frequency ventilation has been tried in adults with ARDS and in infants with hyaline membrane disease in hopes that adequate oxygenation and ventilation could be achieved with lower airway pressures than with conventional mechanical ventilation and PEEP. Conflicting results have been reported in these situations, and whether HFV offers a definite advantage remains to be established.

Problems that have been encountered with high-frequency ventilation include difficulties in humidifying the inspired air adequately. Mucosal injury and increased pulmonary secretions have been encountered. Conventional alarm systems for detecting apnea, inadequate $V_T$, and excess airway pressure are not applicable in HFV. Although there are now ventilators available commercially that are capable of delivering HFV, there are still no well-established guidelines to aid the clinician in deciding which of the several different ventilator types to choose from or what $V_T$ or rate is best for a given patient.

At this point, it seems unlikely that HFV will replace conventional mechanical ventilation in the majority of patients. With further refinements in technology and greater understanding of the physiology involved, however, it is

probable that the number of indications for HFV will expand and that ventilator designs and settings will become more standardized.

# Chapter 8 - Thoracentesis

**David S. Ross**

The term *thoracentesis* is derived from the Greek *thorakos* (chest) and *kentesis* (to pierce). Although a broad definition could include the introduction of any object into the chest, including thoracostomy tubes, common usage is confined to the temporary insertion of a needle or small catheter into the pleural space. Traditionally, thoracentesis is considered to be the method of removing a pleural effusion for diagnostic or therapeutic purposes. In the emergency situation, the removal of air from the pleural space (e.g., from a tension pneumothorax) may also be referred to as thoracentesis. In this chapter, both aspects are discussed. (Tube thoracostomy and the use of catheter drainage for longer periods of time are discussed in Chapter 9) .

Thoracentesis may be performed whenever the appropriate indications are present and suitable equipment is available. Because a tension pneumothorax may quickly cause death, all physicians should be familiar with its clinical appearance and the appropriate indications and techniques for relief of this life-threatening complication. In many communities, paramedical and nursing personnel are also trained in needle or catheter thoracentesis for treatment of tension pneumothorax. Removal of pleural fluid by thoracentesis may be performed by any physician experienced with its indications, precautions, and techniques. It may be performed in the emergency department (ED) or on medical and surgical floors.

The pleural space is a potential space between the visceral and parietal pleura that contains a thin physiologic layer of pleural fluid. With normal inspiration, a negative pressure is developed within the thorax and is transmitted through the pleural space to the pulmonary parenchyma, allowing a normal influx of air. During normal expiration, the elasticity of the pulmonary parenchyma and chest wall allows exhalation.

If fluid, blood, or air accumulates in the pleural space, normal ventilatory mechanisms may be affected. If the volume of fluid or air is large, respiratory compromise may be the result. If the accumulation is rapid and progressive (e.g., tension pneumothorax), there may be cardiovascular compromise in addition to severe respiratory effects. The underlying etiology of an effusion also influences the severity of symptoms.

## BACKGROUND

Thoracentesis (originally called *paracentesis thoracis*) was first described by Hippocrates for relief of empyema. [1] Various operative approaches using trocars or open drainage were advocated during the ensuing centuries. Professional wound suckers who assisted with drainage were replaced by the aspiration syringe, described in 1674. Anel reported the first

successful evacuation of a pneumothorax in 1707. [2] Laennec used thoracentesis for the relief of an apparent pneumomediastinum with a possible associated tension

pneumothorax. [3]

In the 19th century, more interest developed in thoracentesis. Boerhaave advocated the use of a flexible tube for evacuation of a hemothorax. [2] Bowditch provided the first description of thoracentesis in the American medical literature in 1851. [4] Hunter adapted the newly developed hypodermic needle into a modern instrument for thoracentesis in 1859. An underwater seal was later designed by Playfair. [2] Hewett described continuous pleural drainage for empyema in 1876. [5]

Antiseptics and improved sterile technique enabled widespread successful use of thoracentesis in the 20th century. In World War II, thoracentesis and chest drainage replaced routine thoracotomy for most chest injuries, and during the Korean conflict, repeated thoracentesis was advocated for penetrating chest wounds. [3] [6] At the time of the war in Vietnam, the improvement in thoracostomy tubes made them more effective, and tube thoracostomy came to be preferred to simple or repeated thoracentesis.

# INDICATIONS

In the emergency setting, thoracentesis is most often indicated as a life-saving intervention in cases of suspected tension pneumothorax. It is usually done as a temporizing measure before thoracostomy tube placement. Occasionally, a pleural effusion may require emergency evacuation for therapeutic reasons in the compromised patient. More often, thoracentesis will be done semielectively for diagnostic purposes. Thoracentesis has also been performed for evacuation of a small, stable pneumothorax.

There are two general approaches to performing thoracentesis. The anterior approach is most often recommended for removal of air. The posterior approach is chosen most commonly for removal of pleural fluid. Each is discussed separately with further detail regarding clinical indications. The current indications for each approach are summarized in Table 8-1 .

**Anterior Approach for Evacuation of Air**

**Stable Pneumothorax**

**Etiology.**

Pneumothorax is defined as air within the pleural space. It usually enters from a rent in the airway, but it may also enter through the chest wall or from a perforated hollow viscus. Many pneumothoraces occur spontaneously

in patients predisposed by the presence of such conditions as chronic obstructive pulmonary disease (COPD), asthma, aspiration pneumonia, or malignancy. Others occur without evidence of preexisting lung disease. These idiopathic spontaneous pneumothoraces typically occur in young tall males, and they may be recurrent. [8] [9] They occur more frequently in smokers. [10] Catamenial pneumothorax may occur in women at the time of menses but is rare. [11] Bilateral spontaneous pneumothoraces have been reported. [12] In the emergency department, most pneumothoraces occur secondary to trauma, either blunt or penetrating, and may be associated with a hemothorax. Pneumothorax may also occur iatrogenically secondary to central venous catheterization; cardiopulmonary resuscitation; intubation; mechanical ventilation; positive end-expiratory pressure (PEEP); and any needle insertion into the chest wall, such as thoracentesis, electromyography, and breast or lymph node biopsy. [13] [14] [15] [16] [17] Drug abusers may induce a pneumothorax from "pocket shooting" drugs into the internal jugular veins as well as from a Valsalva maneuver performed to enhance a "high" while smoking marijuana or cocaine. [18] [19]

**Diagnosis.**

Patients with a pneumothorax typically experience dyspnea and pleuritic pain that is localized to the involved hemithorax. Cough may also be present. Symptoms vary greatly depending on the size of the pneumothorax and its etiology as well as any underlying lung disease. Physical findings also vary and may include tachypnea,

tachycardia, diminished breath sounds, and increased hyperresonance to percussion. [9] Subcutaneous emphysema may occur. Increased resonance to percussion of the ipsilateral clavicle has been reported. [20]

Radiographic diagnosis of a pneumothorax is made by noting the presence of a visceral pleural line and the absence of pulmonary markings peripheral to that line. An upright expiratory chest film or a lateral decubitus view with the involved side up may enhance the visibility of a small pneumothorax. In the absence of pleural adhesions, the pleural air is free flowing, so a pneumothorax will assume the apical-lateral position on an upright chest radiograph. Pneumothorax must be differentiated from bullae in patients with COPD. [8]

In the supine patient, a small pneumothorax may collect in several recesses. The most common is an anteromedial collection in which a radiolucent band is seen parallel to and enhancing the heart border. Another common location is subpulmonic, in which a radiolucent band is seen superior and parallel to the diaphragm, outlined by the visceral pleura. [21] [22] Other locations include the costophrenic sulcus and the posteromedial recess. In the former, the sulcus appears deepened ( *deep sulcus sign*), often with an oblique radiolucent band projected across the upper abdomen. In the latter, retrocardiac air is seen outlining a collapsed lower lobe and adjacent structures. Other signs of pneumothorax on the supine chest film include hyperlucency of the hemithorax, depressed diaphragm, double diaphragmatic contour, increased delineation along the inferior cardiac border, and visualization of lobulated pericardial fat at the cardiac apex. [21]

Any of these small pneumothoraces may proceed to a tension pneumothorax. [22] Several additional views may help with their diagnosis, including cross-table lateral, abdominal, and oblique views of the chest. If the patient can be repositioned, the free pleural air will rise, as can be demonstrated

on a semirecumbent, upright, or lateral decubitus film. Computed tomography (CT) of the abdomen may demonstrate the pneumothorax. [23] Some suggest performing a limited CT of the lower chest of the major trauma patient, particularly when the patient is having a CT for evaluation of other trauma. [24]

The size of a pneumothorax is often underestimated because volume is a cubic measurement and is not always appreciated by viewing its linear dimensions. An accurate nomogram (see Chapter 9) has been designed for determining pneumothorax size. [25] However, in the ED, from a practical standpoint, categorization of pneumothorax size may be adequate. Pneumothoraces may be functionally categorized as small (marginal), moderate, and large (massive). [26]

**Treatment.**

The usual treatment for a pneumothorax is tube thoracostomy, as discussed in Chapter 9 . Conservative management has been advocated in selected cases. [27] Stable spontaneous pneumothoraces (<20%) are commonly absorbed gradually at the rate of 1.25% daily. [28] This absorption will be enhanced by the administration of oxygen. Small

or marginal stable spontaneous pneumothoraces may be observed for resolution, [8] although some advocate thoracentesis to hasten the resorption and increase patient comfort. [29] In a Detroit study, patients with simple pneumothoraces of varying sizes were treated successfully with catheter aspiration, followed by a 6-hour observation period and discharge from the ED; this was successful in 76% of cases. [30] Similar catheter aspiration and outpatient management proved successful in self-inflicted pneumothoraces among "pocket shooters." [18] Small pigtail catheters and small-bore thoracostomy tubes have also been used successfully to treat pneumothoraces, with the use of the Seldinger (guide wire) technique. [31] [32] [33] [34] (For further discussion of the Seldinger technique for vascular access see Chapter 21.)

**Tension Pneumothorax**

**Mechanism.**

A tension pneumothorax is marked by the progressive collection of air in the pleural space through a rent in the airway, with subsequent increasing pleural pressures and often a shift of the mediastinum away from the side of the pneumothorax. During inspiration, negative intrapleural pressure facilitates flow into the pleural space. During expiration, air is less able to exit the pleural space in the patient with a tension pneumothorax, because of the relative compression of the bronchioli and alveoli and subsequent collapse of the rent in the airway (a result of positive intrathoracic pressure). This creates a one-way valve mechanism, which favors collection and trapping of additional air in the pleural space.

As the volume of intrapleural air continues to expand, the intrapleural pressure rises. This pressure is transmitted against the lungs, causing a continued decrease in functioning lung volume. First the ipsilateral and then the contralateral lung becomes compressed. Resultant parenchymal collapse leads to respiratory compromise as ventilation-perfusion mismatch develops and hypoxia and acidosis ensue. In addition, the increase in the volume of the intrapleural air causes a shift of the mediastinum away from the side of the tension pneumothorax. There may be some decrease in the systemic venous return because of a combination of increased intrathoracic pressure and mechanical collapse of the venae cavae. Originally, it was felt that compromised venous return was the primary cause of diminished cardiac output that led to cardiovascular collapse. Animal studies, however, suggest that progressive hypoxia and $CO_2$ retention may be the primary mediators of cardiovascular depression and collapse. [35] [36] The rapidity with which these events occur is variable. They can proceed quickly and lead to death in a matter of minutes. Therapeutic intervention may often be necessary before full diagnostic evaluation can be carried out.

**Etiology.**

A tension pneumothorax may develop as a result of any of the usual causes of pneumothorax described earlier (see also Chapter 9) . It may develop either primarily as a complication of a previously stable pneumothorax or as a result of positive-pressure ventilation. Although occasionally occurring in the patient with spontaneous pneumothorax, it is seen more often in patients following trauma and may occur

following instrumentation of the chest, such as during central line insertion. It has been reported following incorrect placement of a nasogastric tube in an elderly patient. [37] Certain factors may predispose to the development of a tension pneumothorax in a patient with an otherwise stable pneumothorax. A major predisposing factor is the use of positive-pressure ventilation, either by bag-valve devices or by mechanical ventilators. [38] The addition of PEEP may further increase the risk of development of a tension pneumothorax. [39] Likewise, cardiopulmonary resuscitation may predispose to the development of a tension pneumothorax. [8]

**Clinical diagnosis.**

Tension pneumothorax should always be suspected in any patient in whom sudden respiratory or cardiac deterioration occurs. Development of sudden difficulty ventilating a patient should alert the clinician to the possibility of tension pneumothorax. [8] The clinical presentation in the patient who is awake includes the sudden development of dyspnea, agitation, or diminished consciousness. Tachypnea, tachycardia, hypotension, cyanosis, and diaphoresis may be present and may progress to cardiac or respiratory arrest. The following classic constellation of findings may be seen, although they are not necessarily uniformly present: tympany to percussion, decreased breath sounds over the involved hemithorax, tracheal deviation toward the contralateral side, and the presence of an overinflated, immobile, ipsilateral hemithorax. Jugular venous distention may also be seen. Other signs of chest trauma or respiratory distress should prompt one to consider the possibility of an underlying pneumothorax with potential tension.

In the patient whose condition suddenly deteriorates, other diagnostic considerations should include massive pulmonary embolus, pericardial tamponade, pneumomediastinum, respiratory failure from reactive airway disease, and myocardial infarction. Traumatic diaphragmatic hernia has also been reported to simulate a tension pneumothorax. [40] The patient with a tension pneumothorax who is being ventilated mechanically will show signs of increased airway resistance, evidenced by increased ventilatory pressures, prolonged inspiratory times, elevated central venous pressure, and elevated pulmonary artery pressure. [39]

When the patient is in extremis, the diagnosis should be made by needle or catheter thoracentesis. The patient will show clinical improvement following thoracentesis. The successful relief of a tension pneumothorax is also marked by the rapid efflux of air through the thoracentesis needle during both inspiration and expiration. If a syringe (ideally premoistened) is attached to the thoracentesis needle, the plunger may be driven outward if sufficient pressure has developed. Likewise any drainage apparatus that directs the

efflux of air through a water seal will reveal vigorous bubbling of air in inspiration as well as expiration until the high-pressure air has been released. In a similar manner, a flutter-valve apparatus attached to the needle may continue to show evidence of massive air efflux. If an intubated patient is being ventilated, *diagnostic tube thoracostomy is* preferred to thoracentesis when time permits. There is a theoretical risk of creating a tension pneumothorax by indiscriminate thoracentesis in a patient who is

receiving positive-pressure ventilation.

**Radiologic diagnosis.**

Withholding treatment of a tension pneumothorax until radiographic confirmation is made is not advised except in the following circumstances: in patients whose conditions are stable with only moderate respiratory compromise; in patients in whom tension pneumothorax is suspected but physical evidence is lacking; in patients in whom other likely conditions are being considered, such as a ruptured diaphragm, in which needle decompression may be relatively contraindicated; and in patients in whom portable chest radiographs may be completed immediately.

A patient who has even the most remote possibility of a tension pneumothorax should *never be sent to the radiology suite unless accompanied by a physician* who is prepared to perform immediate thoracentesis or tube thoracostomy. Despite an increased awareness of the possibility of a tension pneumothorax on clinical grounds, the diagnosis is often not recognized until a chest film has been taken. [41]

Radiographic diagnosis is made by noting the presence of the usual signs of pneumothorax described previously, combined with a flattening of the diaphragm and a shift of the mediastinum away from the side of the pneumothorax. [8] In most cases, even in the supine patient, tension pneumothorax is easily diagnosed. Several exceptions exist. In the case of bilateral pneumothoraces, no mediastinal shift may be seen. In this case, tension pneumothorax may be diagnosed clinically on decompression of the chest. Localized areas of tension pneumothorax may occur secondary to adhesions. In patients with adult respiratory distress syndrome (ARDS) on PEEP, localized subpulmonic or paracardiac tension pneumothoraces have been reported despite the presence of thoracostomy tubes. [42] These cases will be suspected clinically because of the presence of increased respiratory pressures and diagnostic criteria for localized pneumothorax discussed earlier, with flattening of the cardiac border and a depression or contour change of the diaphragm.

**Treatment.**

Treatment of a tension pneumothorax should begin as soon as it is recognized clinically. It should be emphasized that although *the preferred and definitive treatment of a tension pneumothorax is immediate tube thoracostomy*, [43] this may not be possible in many clinical settings. If a patient's condition deteriorates suddenly and rapid tube thoracostomy is not possible immediately, thoracentesis is an appropriate temporary treatment and may be life saving. Thoracentesis is most commonly and safely performed by simple needle or catheter aspiration in the midclavicular line, second or third intercostal space. Once a tension pneumothorax is confirmed by this method, a thoracostomy tube should be placed as soon as possible (see Chapter 9) . This is particularly important in the patient on positive-pressure ventilation.

Thoracentesis may also be used in the out-of-hospital care setting, when a patient in extremis is suspected of having a tension pneumothorax. To facilitate the continued

drainage of the pneumothorax, an expedient flutter valve, underwater seal, or commercially available one-way valve may be attached. [44]

McSwain has developed a self-retaining catheter and trocar (McSwain dart, Medical Dynamics, Inc.) that can be placed in the chest and attached to a drainage system. [45] Although this apparatus has been suggested as an alternative to needle or catheter placement, it may be associated with increased risk of pulmonary injury, particularly if placed incorrectly when a pneumothorax is not present [46] (see Chapter 9) . Use of a guide wire-directed minicatheter is currently preferred to use of a minitrocar system. [32] [33] [34]

## Contraindications

In clinical situations in which a tension pneumothorax is suspected, several relative contraindications to the use of thoracentesis are important to remember. If tube thoracostomy is readily available, it may be the preferred procedure, and thoracentesis may only serve to delay the more definitive treatment. In patients who are being ventilated manually or by respirator, extreme caution should be exercised when performing thoracentesis. If the presumptive diagnosis of a tension pneumothorax is incorrect, the insertion of a thoracentesis needle may actually create a pneumothorax, which may be converted into a tension pneumothorax by the positive-pressure ventilation.

An absolute contraindication to thoracentesis is the insertion of a needle through an area of infection. [8] In such cases, an alternate insertion site should be selected. In patients who have bleeding diatheses or who are on anticoagulants, thoracentesis for evacuation of a stable, small pneumothorax may be relatively contraindicated, with observation being the preferred treatment.

## Equipment

The equipment needed to perform rapid thoracentesis for tension pneumothorax or aspiration of a spontaneous pneumothorax is listed in Table 8-2 . Because several techniques are described, the necessary equipment for all techniques is included in this list. Evacuation of a tension pneumothorax can be accomplished by insertion of a needle only, a through-the-needle catheter, or an over-the-needle catheter. Although the needle insertion technique can be performed most rapidly, the catheter insertion techniques may theoretically be safer, allowing continued drainage of the relieved tension pneumothorax without the presence of a rigid needle in the thorax. The drawbacks to the use of a catheter are the possibility of the catheter's crimping or collapsing as well as the increased resistance to drainage caused by the catheter's length. The catheter technique is recommended in relief of tension pneumothorax in the out-of-hospital setting. [47] Likewise, when evacuating a simple stable pneumothorax, the catheter techniques may be preferred because they are less likely to pierce the expanding lung. Small thoracostomy tubes and pigtail catheters may be used for the stable pneumothorax and are placed using the Seldinger technique (see also Chapter 21) .

## Procedure

The anterior thoracentesis approach is used primarily for relief of a tension pneumothorax and evacuation of a simple

pneumothorax. Because treatment is urgently required in the first case, the procedure chosen should be performed in an appropriately expedient manner. Likewise, the amount of preparation and equipment needed is dictated by each particular clinical situation. Informed consent is likely to be impossible to obtain in cases of tension pneumothorax, but an attempt to secure it may be considered in patients with a stable pneumothorax.

### Insertion Site and Patient Position

The conventional approach has been to evacuate tension pneumothoraces by using the anterior approach, with the patient in a supine position and the head of the stretcher elevated 30°. The recommended insertion site is the second intercostal space in the midclavicular line (Fig. 8-1) (Figure Not Available) . The rationale for this approach is that free pleural air will rise to the anterior upper chest. With a tension pneumothorax, however, the collapsed lung is moved away from the entire ipsilateral chest wall, making a lateral approach also possible. If the patient is in a supine position and if the anterior chest is obscured (e.g., subclavian vein catheter bandage, chest monitoring leads, subcutaneous emphysema) or if a chest wall infection is present, a lateral approach may be more practical. The lateral approach is accomplished by inserting the needle into the fourth or fifth intercostal space in the midaxillary or anterior axillary line. This location can be identified quickly in males by extending the horizontal nipple line laterally into the axilla. In females who have large breasts, reliable approximation can be made by extending an

|    Sterile intravenous tubing with water-filled basin |
|    Syringe (30 to 50 mL) with 3-way stopcock |

* Requires additional equipment for Seldinger technique (see Chapters 9 and 21).

**Figure 8-1** (Figure Not Available) For relief of a pneumothorax, the second intercostal space in the midclavicular line is commonly used. The head of the stretcher is elevated 30°. The midaxillary line, fourth or fifth intercostal space site, has been used for thoracentesis of pleural fluid (see text). *(From Fishman NH: Thoracic Drainage: A Manual of Procedures. Chicago, Year Book Medical Publishers, 1983, p 26. Reproduced by permission.)*

imaginary horizontal line between the inferior tips of the scapulae laterally into the axilla.

There are two major problems when the lateral approach is chosen. The first is the greater risk of parenchymal injury if neither a tension nor a large pneumothorax is present. The second problem is the danger of adhesions. Previous empyema, hemothorax, tuberculosis, and other inflammatory processes may cause pleural adhesions, which frequently occur in dependent portions of the thorax. Therefore, the anterior approach is theoretically safer and is recommended for most cases in which relief of tension pneumothorax is required. Likewise, for the evacuation of a simple stable pneumothorax, the anterior approach is recommended unless a loculated pneumothorax dictates an alternate approach.

**Needle or Catheter Insertion for Evacuation of Air**

**Patient preparation.**

The patient is positioned as previously discussed. An explanation of the procedure is appropriate if the patient is awake, but it should not delay the procedure. Because the patient is usually in extremis, sedation is contraindicated. Restraining the patient may be necessary if the patient is hypoxic and confused. Oxygen should be administered. When time permits, the insertion site is swabbed rapidly with povidone-iodine or another suitable antiseptic. If a stable pneumothorax is being evacuated, an appropriate explanation and a careful preparation of the sterile field is indicated.

**Anesthesia.**

Local anesthesia is usually unnecessary in the case of relieving a tension pneumothorax and will only delay the procedure. If the patient has a slowly progressive tension pneumothorax or a stable pneumothorax and is not in extremis, local anesthesia with 1% lidocaine or its equivalent may be used. It is administered through a 5- to 10-mL

syringe with a 25- to 27-ga needle. An intradermal wheal is raised over the upper edge of the third or fourth rib after localization with palpation. Anesthetic is infiltrated down to the periosteum. The needle is then withdrawn.

**Insertion techniques.**

If time allows, a 14- to 20-ga needle is selected and attached to a 5- to 10-mL syringe premoistened with saline. The third rib is again identified by palpation. The needle is inserted perpendicularly in the midclavicular line over the upper edge of the rib. As the rib is encountered, the needle is "walked" over the superior aspect of the rib and into the lower portion of the second intercostal space. This approach should avoid the intercostal vessels positioned near the lower border of each rib, as indicated in Figure 8-2 (Figure Not Available) . The syringe is gently aspirated as the needle is advanced. A "pop" may be felt as the pleural space is entered and air is encountered. A pneumothorax under tension may create enough pressure to drive the plunger of a premoistened syringe the length of the barrel without manually withdrawing it. If the needle has been inserted without a syringe attached, a rush of air exiting the chest may

be heard in inspiration as well as during expiration. Either of these findings will confirm the presence of a tension pneumothorax. Inserting a needle without an attached syringe or other drainage device invites the possibility of creating a pneumothorax if none is already present. If any pneumothorax is confirmed, a one-way drainage device should be attached as soon as possible.

Alternate methods of relief of a tension or stable pneumothorax include the use of standard intravenous needle and catheter insertion sets (Fig. 8-3) (Figure Not Available) . This can be accomplished by attaching the syringe to the hub of an *over-the-needle catheter* (with a 14- to 18-ga needle). Larger sizes should be chosen for a tension pneumothorax. A small scalpel blade may be used to pierce the skin at the entry site to facilitate catheter entry. The pleura is entered through the second or third intercostal space, as previously described,

**Figure 8-2** (Figure Not Available) "Walking" the anesthetic needle over the superior aspect of the rib. *(From Fishman NH: Thoracic Drainage: A Manual of Procedures. Chicago, Year Book Medical Publishers, 1983, p 28. Reproduced by permission.)*

**Figure 8-3** (Figure Not Available) Insertion technique for through-the-needle and over-the-needle catheters. Separate intercostal spaces depict the steps *(A-C)* that occur at a single intercostal space. *(From Fishman NH: Thoracic Drainage: A Manual of Procedures. Chicago, Year Book Medical Publishers, 1983, p 30. Reproduced by permission.)*

and the catheter is advanced over the needle into the pleural space. The needle is then removed, and the syringe or another drainage device is attached to the hub of the catheter. A tension pneumothorax is confirmed by the same findings as those discussed earlier. The catheter may be secured with sutures. A drainage system is then attached.

A *through-the-needle catheter* (with a 14- to 16-ga needle) of the shortest available length may also be used. The larger diameter should be chosen for a tension pneumothorax. Once the needle has entered the pleural space, the catheter is advanced fully into the thorax through the needle. The needle is then withdrawn, and a drainage device is attached to the catheter hub. The needle guard should be attached to prevent a laceration of the catheter by the surrounding needle. The catheter may be secured by suturing it to the chest wall. A one-way drainage system should be attached.

For evacuation of a *simple stable pneumothorax*, either the over-the-needle or through-the-needle technique may be used. In these cases, it is important to attach a one-way drainage system before piercing the chest, because the pneumothorax will not be under pressure, and an exposed catheter lumen may enlarge the pneumothorax. Commercial thoracentesis kits and specialized equipment may also be used (see Needle or Catheter Insertion for Evacuation of Fluid).

The Seldinger technique may also be used to insert a pigtail catheter (6.5 to 8.5 Fr) or a small chest tube (approximately 8 Fr) for evacuating a stable pneumothorax. A 16- to 18-ga needle is attached to a syringe and inserted into the

pleural space until air is encountered, as described previously. While holding the needle securely, the syringe is removed, and the hub of the needle is covered with a gloved

finger. A fine, flexible-tipped guide wire is inserted through the needle and advanced into the pleural space. The needle is withdrawn, leaving the wire in place. A small scalpel blade is used to pierce the skin adjacent to the guide wire. As an option, a dilator may be threaded over the wire and then removed after enlarging the opening. A pigtail catheter or small chest tube is threaded over the exposed guide wire and gently advanced into the pleura to an adequate depth such that all side openings are well within the chest. The wire is then removed, and the catheter should be secured to the chest wall. The catheter should be attached to a drainage device as soon as possible.

Initially, air may be evacuated with a 60-mL syringe and a three-way stopcock. If expansion is incomplete, continuous suction may be used (see Chapter 9) . The expanding lung may kink the catheter, requiring placement of a larger catheter. The physician may also instruct the patient to change position (e.g., supine to sitting) or cough to help free the catheter and permit complete lung expansion.

**Drainage.**

After the diagnosis of a pneumothorax has been made, drainage should be instituted. In the case of a tension pneumothorax, drainage should be continued until a thoracostomy tube can be placed. Continuous drainage can be accomplished by attaching the distal end of an intravenous tubing set without one-way valves to the needle or catheter hub. The proximal end of the intravenous tubing is placed under water in a basin to create an underwater seal. This prevents air from entering the pleural space. An alternative is to attach a commercial flutter valve, such as the Heimlich valve. An expedient drainage device may also be made using a premoistened finger cut from a sterile examination glove (Fig. 8-4) (Figure Not Available) . The cut edge of the glove finger will act as a one-way flutter-valve.

Any of the previously mentioned techniques may be used for drainage of a stable pneumothorax. Evacuation by attaching a three-way valve to a large (30 to 50 mL) syringe may facilitate the removal of air without creating a danger of increasing the pneumothorax size. Care must be taken to exert gentle negative pressure when aspirating air, because greater negative pressure may cause postexpansion pulmonary edema (see Complications). If a pigtail catheter or small chest tube has been placed, a standard pleural drainage system may be used (see Chapter 9) .

If a tension pneumothorax is found and confirmed by any of the aforementioned methods, a thoracostomy tube should be placed as soon as possible. A chest film is also indicated following thoracentesis or tube thoracostomy to confirm the successful relief of the pneumothorax, absence of hemothorax or other complications, and (if performed) thoracostomy tube placement. This confirmation is best obtained with an upright expiratory chest film.

## Posterior Approach for Evacuation of Fluid

**Pleural Effusion**

**Physiology.**

Pleural fluid is normally created as a result of several physiologic mechanisms, including hydrostatic pressure, colloid oncotic pressure, and intrapleural pressure. [8] [48] With normal pleural homeostasis, the hydrostatic pressure generated by the systemic capillaries across the parietal pleura is greater than the hydrostatic pressure generated by the pulmonary capillaries across the visceral pleura. Because the colloid oncotic and intrapleural pressures exert symmetrical forces, a gradient is created that allows for the formation of normal fluid at the parietal pleura and absorption by the visceral pleura. Lymphatic flow also facilitates absorption. A summary of the homeostatic forces involved is shown in Figure 8-5 (Figure Not Available) .

The integrity of this system can be disrupted by changes in hydrostatic pressure, colloid oncotic pressure, intrapleural pressure, lymphatic flow, capillary permeability, and pleural fluid surfactant composition. [48] [49] Fluid can accumulate because of two processes, transudation and exudation. Transudation may occur from increased pulmonary capillary pressure, as in left ventricular failure, or from decreased colloid oncotic pressure secondary to hypoalbuminemic states, as in

**Figure 8-4** (Figure Not Available) Use of a needle and a sterile finger cot or a finger from a sterile glove to fashion a one-way (flutter) valve for emergency evacuation of a tension pneumothorax. A small opening is made in the free end of the glove to allow air to escape during expiration. *(Redrawn from Cosgniff JH: An Atlas of Diagnostic and Therapeutic Procedures for Emergency Personnel. Philadelphia, JB Lippincott, 1978, p 243.)*

**Figure 8-5** (Figure Not Available) Diagrammatic representation of the pressures involved in the formation and absorption of pleural fluid. *(From Fraser RG, Pare JAP: Diagnosis of Diseases of the Chest. Philadelphia. WB Saunders, 1970, p 65. Reproduced by permission.)*

the nephrotic syndrome and cirrhosis. Structural abnormalities, such as peritoneal-pleural communications in cirrhotic patients with ascites, have been reported. [50]

The exudation of fluid into the pleural space may occur as the result of abnormalities, such as changes in surfactant or altered capillary permeability seen with inflammatory disease, infection, pulmonary infarction, respiratory distress syndrome, and neoplasm. [8] [48] [49] Lymphatic malignancy may decrease fluid resorption. Likewise, trauma to the thoracic duct, esophagus, or vascular structures leads to the direct flow of the contents of these structures into the pleural space.

**Etiology.**

Numerous etiologies may account for the formation of abnormal pleural fluid. Rapid or relatively acute accumulations may be seen with hemothorax, esophageal rupture, pulmonary infarction, infection, empyema, obstructive uropathy, thoracic duct injury, or iatrogenic causes (such as intrapleural placement of a subclavian vein catheter). Chronic effusions are also commonly seen in many disease states. The most common atraumatic causes of effusion are congestive heart failure, infection, and neoplasm. [8]

Effusions due to pneumonia are referred to as *parapneumonic.* Massive effusions causing mediastinal shift (tension hydrothorax) due to malignancy, dialysis, and following iatrogenic intrapleural infusion of parenteral hyperalimentation solution have been reported. [51] [52] [53] Traditionally, effusions have been classified as transudates or exudates. Transudates typically have a low specific gravity and protein concentration. Exudates usually have an increased specific gravity and high protein concentration (see Pleural Fluid Analysis). Common causes of effusions are listed in Table 8-3 .

**Clinical diagnosis.**

A pleural effusion may be asymptomatic or may produce varying degrees of dyspnea or pleuritic pain. Other symptoms, such as cough, fever, weight loss, or edema, may be present and may be related to the underlying cause of the effusion.

The physical signs of pleural effusion vary according to its size. Small effusions do not usually produce physical findings. Moderate-sized effusions may produce physical findings over the area of the effusion. A pleural friction rub may be present. Breath sounds may be diminished, there may be dullness to percussion, and tactile fremitus may be decreased. Occasionally, decreased chest excursions are evident. In very large effusions, breath sounds may change from vesicular to bronchovesicular, gradually becoming absent as compression of the underlying lung occurs. A tension hydrothorax may produce mediastinal shift with tracheal deviation, displacement of the cardiac impulse, and bulging of the intercostal spaces. [52] [53]

**Radiographic diagnosis.**

The radiographic findings of pleural effusions vary with the location and amount of fluid present. Slight elevation of the hemidiaphragm or lateral displacement of the diaphragmatic dome on the posteroanterior chest film suggests a small subpulmonic effusion. Blunting of the costophrenic angle may be seen on an upright chest film and represents at least 175 mL of fluid. [54] A fluid level with an upwardly concave meniscus indicates a

considerably larger effusion. The higher level of the meniscus laterally is due partly to the fact that the lung exerts pressure outward from the hilum, pushing the fluid toward the periphery. [55] In addition, the increased density of the fluid viewed tangentially at the edge of the chest renders it visible, whereas the fluid located medially may not be of sufficient depth to be visualized. A fluid level without a meniscus is indicative of a coexisting pneumothorax. A massive pleural effusion with contralateral shifting of the mediastinum and diaphragmatic inversion indicates a tension hydrothorax. [53]

Lateral decubitus views of the chest with the involved side down may help to identify small amounts of pleural fluid. [56] Comparison of bilateral decubitus views may help to differentiate fluid from other densities as well as enable viewing underlying lung previously obscured by pleural fluid. [57]

On a supine anteroposterior film, a generalized increased density over the lung field(s), costophrenic blunting, apical capping, widening of the minor fissure, and obscuring of the hemidiaphragm may be suggestive of a pleural effusion. [58] A pleural effusion may be differentiated from an infiltrate by the lack of air bronchograms and the absence of a "silhouette sign" obscuring the heart border. [8] A lateral decubitus or upright chest film helps to confirm this diagnosis.

Other findings may be seen in various views, including thickening of the pleural fissures. A middle lobe "step" has been described on the upright lateral film in which the major and minor fissures outline the middle lobe while the lower lobe is compressed. [8] Loculated effusions along the pleural border due to adhesions from previous hemothorax or empyema may be seen occasionally. Elliptical thickening of the fissures is suggestive of loculated effusions. Ultrasonic examination of the chest may help differentiate loculated effusions from solid tumors as well as help localize fluid for thoracentesis. [59] A CT of the chest may help evaluate underlying pathologic findings in the presence of an effusion. [60] It may also help identify subpulmonic effusion, atelectasis, and subphrenic fluid. [61] [62]

**Treatment.**

Management of pleural effusions must be directed toward treatment of the underlying condition. In most cases, thoracentesis is indicated for diagnostic purposes. Exceptions to the need for diagnostic thoracentesis may be made for congestive heart failure or for the stable, previously diagnosed effusion in which the cause is clear. Thoracentesis may be withheld in these situations if the effusion responds to medical management. [63] In cases in which tuberculosis or malignancy is suspected, pleural biopsy may also be indicated. The timing of the thoracentesis and biopsy should be coordinated.

Repeated thoracentesis has been recommended by some to monitor the pH of a parapneumonic effusion; a decreasing pH may indicate progression to a complicated parapneumonic effusion that requires thoracostomy tube drainage. [64] Other conditions diagnosed by thoracentesis, such as empyema or hemothorax, usually require thoracostomy tube insertion to facilitate more thorough evacuation. Likewise, chylothorax due to thoracic duct trauma is often managed by thoracostomy drainage

and total parenteral hyperalimentation. [65] A ruptured esophagus usually requires thoracotomy and surgical repair.

Another major indication for thoracentesis is evacuation of a large symptomatic pleural effusion. If the effusion is quite large, has accumulated rapidly, or causes inversion of the diaphragm, the effusion itself may seriously impair respiratory function by decreasing lung volume and increasing shunting. [66] Tension hydrothorax likewise causes significant respiratory compromise and may impair venous return. [67]

In the conditions mentioned previously, removing a large amount of pleural fluid may provide significant therapeutic benefit by improving oxygen saturation, improving the alveolar-arterial oxygen gradient, decreasing shunting, and improving vital capacity. [68] [69] Although removing a maximum of 1000 to 1500 mL has been a general rule of thumb, as it was thought to prevent postevacuation pulmonary edema, larger amounts may be removed safely by monitoring the pleural pressures and maintaining gentle negative pressure (see Complications). In cases of intractable malignant effusions, placement of a pleuroperitoneal shunt may be useful. [70]

**Hemothorax**

Historically, repeated thoracentesis was used initially to evacuate hemothoraces. With the advent of effective tube thoracostomy, however, this method has become nearly obsolete. Several major arguments against this practice can explain its decline. Repeated violation of the pleura and persistence of the hematoma may increase the risk of infection. The effectiveness of evacuation is inferior to that of tube thoracostomy with continuous suction. Likewise, thoracostomy tube drainage allows better monitoring of the rate of bleeding. Failure of complete resorption of a hemothorax may create a "fibrous peel," or fibrothorax, which can lead to restricted ventilation and may subsequently require open thoracotomy and decortication. Finally, tamponade of the bleeding source may theoretically be enhanced by complete expansion of the lung.

Nevertheless, some investigators suggest that thoracentesis may be used safely in select cases, such as a small stable traumatic hemothorax. [71] In one series, thoracentesis was used in traumatic hemothorax for 104 of 502 patients, with only 1 patient requiring subsequent thoracotomy for fibrothorax. [72] In a second series of 130 patients, thoracentesis was used for hemothorax evacuation in 48 patients, with 10% developing fibrothorax. [73] The results were poorest in patients with hemopneumothorax. Other isolated successful uses of thoracentesis in cases of nontraumatic hemothorax have been reported, including in Osler-Weber-Rendu disease and spontaneous hemothorax in the newborn. [74] [75] (Traumatic hemothorax is discussed in Chapter 9.)

## Contraindications

The removal of pleural fluid by thoracentesis should be avoided in patients with a bleeding diathesis and in those on anticoagulants before correction of the clotting deficits. [8] Thoracentesis is also contraindicated unless performed under ultrasound or fluoroscopic guidance if the patient has an ipsilateral ruptured diaphragm. Extreme

caution should be used when thoracentesis is being performed in a patient who has pleural adhesions, such as from previous tuberculosis, hemopneumothorax, or empyema, because of the danger of piercing the closely approximated visceral pleura and lung. Should there be an infection of the chest wall, thoracentesis is contraindicated unless an alternate puncture site without soft-tissue infection can be selected. In patients who require removal of large quantities of fluid, needle insertion techniques

may be relatively contraindicated because of an increased risk of parenchymal damage. [8] Of note, Godwin and Sahn report a thoracentesis series in mechanically ventilated patients with a mean fluid withdrawal of 840 mL. [76] Only 2 of 32 procedures resulted in a pneumothorax. Hence, mechanical ventilation alone should not represent an absolute contraindication. Nonetheless, the operator must closely monitor the patient in such situations, because any pneumothorax is at great risk for becoming a tension pneumothorax.

## Equipment

For removal of fluids, more equipment is necessary than that required for aspiration of a pneumothorax. The additional equipment permits thorough patient preparation, more adequate anesthesia, controlled evacuation of fluid, and careful collection of specimens. In Table 8-4 , the basic and alternative equipment is listed. The simple needle method has the potential risk of perforating the visceral pleura as the fluid is withdrawn, whereas the catheter of narrow diameter and long length may limit the removal of thick, tenacious fluids. Catheters also have the drawback of crimping if not handled carefully.

Either needle insertion or catheter insertion techniques may be used for diagnostic thoracentesis when only a relatively small amount of fluid is being withdrawn. Needle insertion techniques may increase the risk of parenchymal injury when large quantities of fluid are removed for therapeutic purposes. [8] Likewise, catheter insertion techniques may be preferable when only a small amount of fluid is available and the risk of contact with the lung is greater.

Pigtail catheters also have been used successfully to remove effusions. [32] [33] [77] The Seldinger technique is used to aid in their insertion.

## Procedure

Thoracentesis is generally an elective procedure and should be performed after an adequate number of diagnostic radiographic

Reproduced by permission.)*

studies have been obtained. The procedure should be carried out with sufficient preparation after all available equipment has been tested and under properly controlled circumstances. Informed consent should usually be obtained and documented, according to hospital policy.

The posterior approach is most often recommended when performing thoracentesis for removal of pleural effusions for either diagnostic or therapeutic purposes. A lateral approach may be used in certain circumstances that are described later.

**Insertion Site and Patient Position**

The choice of insertion site for removal of pleural fluid depends on many clinical factors. If the fluid collection is large and if the patient is able to sit upright for a prolonged period, the following approach is recommended: The patient is seated, leaning forward slightly, supported by the back of a chair or a table. Some physicians recommend that the patient's back be vertical to keep the fluid in the dependent posterior chest (Fig. 8-6) (Figure Not Available) . [8] The site chosen for aspiration is the midscapular line or the posterior axillary line at a level below the top of the fluid. This level is best determined clinically at the time of the procedure by the height of dullness to percussion and the decrease in tactile fremitus. [78] A single interspace below this level should be selected.

[8]

A chest film of the patient in an upright position should be taken to diagnose and locate the general position of the effusion, but reliance on the film is less precise than clinical assessment. Radiographic determination of fluid levels may occasionally be misleading, because the position of the fluid changes with respiration and patient position. In addition, one should be reminded that the fluid level seen on a chest film of a patient in an upright position is actually higher

than the bottom of the fluid meniscus. [55] The raised lateral edge of the fluid level represents the height of fluid available at the periphery. An exception to this distribution of pleural fluid occurs when a combined pneumothorax and pleural effusion produces a flat air-fluid level. In all cases, the lowest level recommended for thoracentesis is the eighth intercostal space. The highest level clinically indicated is generally chosen to minimize inadvertent abdominal insertion of the needle. If a catheter has been inserted and insufficient fluid is obtained, the patient can subsequently be repositioned to make the insertion site more dependent. [78]

The following alternative approaches have been described: If the patient is unable to remain seated, a catheter (through-the-needle, over-the-needle, or pigtail) may be inserted into the midaxillary or posterior axillary line in the fourth or fifth intercostal space while the patient is in a supine position (see Fig. 8-1) (Figure Not Available) . [55] It may be prudent to evaluate the height of the fluid both clinically and radiographically in this position before attempting this approach. If the patient can tolerate some elevation, it has been suggested that the patient recline against the raised head of the bed for support while the needle is inserted in the midaxillary or posterior axillary line at the appropriate level. [8] A lower interspace also may be used in these cases. Another suggestion is that the patient lie in a lateral decubitus position with a posterior site chosen for insertion. [8] If the amount of fluid is small and the need for diagnostic analysis is considerable, fluid can be aspirated from beneath the patient in the midaxillary line with the patient in the lateral decubitus position. [79] This technique requires that the patient be placed across an open space between stretchers in such a way that the physician can aspirate from below the patient and between the supporting structures.

For small or loculated effusions, ultrasound-guided thoracentesis may be preferable. [8] [80] Fluoroscopic and CT scan guidance have also been used successfully. [81]

**Needle or Catheter Insertion for Evacuation of Fluid**

**Patient preparation.**

The patient should be placed in the appropriate position, as described previously. Proper explanation of the procedure is essential, when there is adequate time. If the patient is comfortable and cooperative, sedation is not needed. When the patient is uncooperative and in extremis, restraint may be necessary. If the patient is restrained, access to the insertion site must be clear, and one's ability to manage the patient and the airway must not be compromised. Sedation should be avoided if possible. In cases

in which some sedation is essential, extreme caution and careful monitoring must be done; a rapid-acting or reversible sedative agent should be used. Supplementary oxygen by nasal prongs or mask should be given if it is clinically indicated, and it may minimize postevacuation hypoxia (see Complications). A wide area around the thoracentesis site should be prepared, using povidone-iodine or another suitable antiseptic, to allow selection of several intercostal spaces. Sterile towels should be draped around the site. A patent intravenous line should be established, and atropine sulfate for intravenous administration should be available in the event that the patient has a vasovagal reaction.

**Anesthesia and pleural fluid localization.**

Local anesthesia should be used before removal of pleural fluid. A 1% solution of lidocaine or equivalent anesthetic is usually chosen. The anesthetic (5-10 mL) is drawn into a syringe, and a 25- or 27-ga needle is attached. The previously selected insertion site is relocated by palpation. A small skin wheal is raised at the upper edge of the rib. The syringe is withdrawn, and a 3.75-cm, 22-ga needle is attached and then inserted through the wheal toward the upper border of the rib. The subcutaneous tissue and muscle are alternately aspirated and infiltrated as the needle is advanced down to the periosteum of the rib. At this point, the needle is "walked" above the superior edge of the rib. It is then held perpendicular to the chest and, while the aspiration-infiltration process is continued, is advanced through the intercostal space until the pleura is entered (see Fig. 8-2) (Figure Not Available) . A pop may be felt, and fluid should be aspirated to ensure that the pleural space has been reached. If no fluid is encountered, the chosen intercostal space may be too low, and a higher site may be indicated. If air bubbles are encountered, the lung parenchyma may have been entered; the chosen intercostal space may be too high, and a lower site may be indicated. Once fluid is aspirated, a curved hemostat may be applied to the needle at the skin surface, or the needle may be grasped with the thumb and index finger to indicate the proper depth of penetration. [78] The needle and hemostat or fingers should be removed together.

**Needle insertion techniques.**

The following technique is used for diagnostic thoracentesis when a moderate to large amount of fluid is present. A 3.75- to 5-cm, 18- to 22-ga needle is selected. The smaller-diameter needles may decrease the risk of hemothorax and are usually adequate to remove pleural fluid. [8] The needle and a 50-mL syringe are attached to a three-way stopcock. The syringe and needle may be premoistened with heparin. A drainage tube is attached to the stopcock. The lever of the stopcock is set to allow passage of fluid between the needle and the syringe. The depth of the pleural space as determined from the anesthetic needle is now marked on the larger aspiration needle by gently placing a second hemostat or grasping the needle with the index finger and thumb. The pleural space is again entered through the previous anesthetic site while gentle negative pressure is applied. Attention to the indicated depth will prevent insertion of the needle farther than necessary, thus decreasing the chance of lacerating the underlying lung. Fluid is first aspirated with the syringe. The stopcock lever is then turned, and the fluid is expelled through the drainage tube into a sterile container or sterile vacuum bottle or into open specimen tubes. An assistant is needed to handle the

specimen tubes. The process of aspirating and ejecting the fluid through the drainage tubing is repeated until an adequate amount of fluid to accommodate all needed specimens has been drained.

Thoracentesis performed for diagnostic purposes requires removal of 50 to 100 mL. The specimens obtained are listed in Table 8-5 . It is suggested that the appropriate laboratories be contacted to ensure the optimal collection technique for a specific analysis. It may, for example, be best to collect fluid for cytologic analysis in the morning, to ensure examination of freshly obtained cells. Once the desired amount of fluid has been removed, the needle is withdrawn. A sterile dressing is applied over the insertion site. An upright expiratory chest film is taken to ensure that an iatrogenic pneumothorax was not created.

**Catheter insertion techniques.**

An alternative method

of removing the pleural fluid can be accomplished by either of the following techniques.

Catheter insertion techniques (see Fig. 8-3) (Figure Not Available) may be preferable when either small amounts of fluid are present and needed for diagnostic analysis or when large quantities are to be removed for therapeutic relief. [8] An *over-the-needle catheter* (16- to 20-ga needle) is attached to the 50-mL syringe. The syringe may be premoistened with heparin. A small scalpel blade to pierce the skin at the selected insertion site may ease entry of the catheter through the skin. The proper depth of the pleural space is indicated on the catheter by grasping it between a gloved index finger and thumb. The needle and catheter are inserted into the pleural space, as previously described. As fluid is encountered, the needle and the catheter are angled slightly caudally. The catheter is advanced into the pleural space, and the needle is withdrawn. The exposed lumen of the catheter hub is covered with a gloved finger to prevent the entry of air. A three-way stopcock with an attached 50-mL syringe and a drainage tube are again attached to the catheter hub. Fluid is removed following the same process for the needle insertion technique. For diagnostic purposes, 50 to 100 mL of fluid should be adequate. If the purpose of the thoracentesis is therapeutic drainage, the fluid is removed in 50-mL aliquots until the respiratory distress appears to be relieved. Although it has usually been recommended that no more than 1000 to 1500 mL of pleural fluid be removed because of the potential for excessive loss of protein or the risk of postevacuation pulmonary edema, [8] [78] more fluid may be removed with gentle negative pressure. Measuring the pleural pressure frequently, using a manometer, may be appropriate if larger quantities are removed [8] [82] (see Complications). Aftercare is the same for catheter drainage as for needle drainage.

A second alternative method involves the use of a *through-the-needle catheter* (14- to 18-ga needle). The catheter is withdrawn from the needle before the procedure. A three-way stopcock is attached to the catheter hub and adjusted to close the catheter to the passage of air or fluid. The catheter and stopcock are temporarily set aside with sterile technique. The empty outer needle is attached to a 50-mL syringe. The syringe may be premoistened with heparin. The depth is again marked on the needle with a hemostat or index finger and thumb, as previously described, to indicate the depth of the pleural fluid as determined from the anesthetic needle. The needle is inserted into the pleural space through the anesthetized area while constant, gentle, negative pressure is applied. Once fluid is encountered, the needle is held securely as the syringe is detached. Again, it is essential to cover the needle hub with a gloved finger. The needle is then held securely and angled caudally as the catheter is inserted through the needle into the pleural space and advanced its full distance. The needle is withdrawn, leaving the catheter within the chest wall. The needle guard is then attached to the needle tip to prevent shearing off of the catheter. The catheter *must not be drawn back through the needle*, because such action may lacerate the catheter and allow its free entry into the pleural space. The catheter is then held securely within the chest wall without bending or kinking. The syringe is reattached to the stopcock, and the stopcock lever is turned to allow passage of fluid into the syringe. Fluid is withdrawn according to the guidelines described for the previous over-the-needle catheter technique. Should repositioning be needed, care must be taken to avoid crimping the catheter. After an adequate amount of fluid has been withdrawn, the catheter is removed and the entry site is covered with a sterile bandage. A follow-up chest film is again indicated.

**Commercial thoracentesis kits and miscellaneous equipment.**

Commercial prepackaged kits have been developed that provide the general equipment needed to perform thoracentesis for the removal of pleural effusion. Most include the basic equipment previously described. Use of a kit saves time. Some kits include equipment such as drainage bags or applicators for the preparation solution. Others may provide unique equipment such as automatic two-way valves, self-sealing diaphragms, or collection apparatus. [83] In general, their drawbacks may include increased cost and limited equipment within the kit. Some may provide brief instructions on technique. It is recommended that each manufacturer's description of thoracentesis technique be consulted and that the equipment be reviewed to allow assembly of any additional equipment before beginning the procedure. The techniques used should follow the guidelines described earlier, depending on the general type of needle or catheter included in the kits.

Occasionally, specialized equipment that has been developed for other purposes can be used for thoracentesis. An example is an "on-off flow switch" produced in England (Viggo) that has been incorporated into a 13-cm over-the-needle catheter for central venous cannulation. The flow through this catheter may be turned off while the introducing needle is removed and a syringe is attached. [84] If the

catheter is used for thoracentesis, the flow switch may serve to prevent the inadvertent creation of a pneumothorax.

**Pigtail catheter insertion.**

A new method of catheter insertion using the Seldinger technique allows the insertion of small pigtail catheters (6.0 to 8.5 Fr) to evacuate fluid. A 16- to 18-ga needle is attached to a syringe and inserted through the appropriate interspace into the pleural space until fluid is encountered. The needle is held securely as the syringe is removed and the exposed hub of the needle is covered. A small, flexible guide wire is then threaded through the needle, which is angled caudally. The needle is removed while the wire remains within the chest. A puncture is made through the skin next to the guide wire with a small scalpel blade. An optional dilator may be threaded over the wire and then removed to enlarge the opening. The pigtail catheter is inserted over the wire and advanced gently into the chest so that all side openings are well within the pleura. The wire is removed and a stopcock and drainage system are attached to the catheter. The catheter should be attached to the chest wall.

## Pleural Fluid Analysis

Whether fluid is removed for diagnostic or for therapeutic purposes, certain specimens should be sent for laboratory analysis based on clinical indications. [85] Of diagnostic thoracenteses, 92% provide clinically useful information. [86]

Whenever thoracentesis is performed, visual inspection of the fluid should be performed. Bloody or blood-tinged fluid most commonly indicates hemothorax, malignancy, pulmonary infarction, or tuberculosis. White or milky fluid suggests a

chylothorax or chyliform effusion (described later). A thick, purulent fluid, often with a foul odor, indicates an empyema. Other effusions may range from clear, to straw-colored, to turbid (Table 8-6) (Table Not Available) .

Establishing whether an effusion is a transudate or an

| TABLE 8-6 -- Diagnostic Features of Pleural Fluid<br>*From Ross DS: Pleural effusion. In Harwood-Nuss AL, Linden CH, Luten RC, et al (eds): The Clinical Practice of Emergency Medicine. JB Lippincott, Philadelphia, 1990. Reproduced by permission.* |
| --- |
| (Not Available) |

exudate provides useful information. If a transudate is diagnosed, it has been suggested that minimal additional testing will be needed. [87] Typically, transudates have protein levels <3 g/100 mL and a specific gravity <1.016. Exudates have values above these levels. Additional criteria have been advocated that provide a more accurate differentiation. These include (1) a ratio of pleural fluid protein to serum protein of 0.5, (2) a pleural lactate dehydrogenase (LDH) level of 200 IU/mL, and (3) a ratio of pleural fluid LDH to serum LDH of 0.6. Transudates have values below these levels, and exudates have at least one finding above these levels (Table 8-7) (Table Not Available) . [88] These recommendations should be tempered by clinical suspicion. In all cases, fluid should be held for possible additional analysis in the appropriate specimen container (see Table 8-5) . [89]

Cytologic analysis is an extremely important diagnostic tool. If abnormal cellular components of pleural fluid are found, it is highly significant. Cytologic analysis may identify malignancies in >60% of cases, [90] [91] although a repeat tap for repeat cytologic analysis along with assay of tumor markers (e.g., carcinoembryonic antigen [CEA]) may be needed. [92] Many specimens may be needed if the suspicion is high. White blood cell (WBC), differential, and red blood cell (RBC) counts on pleural fluid, however, may provide some general information, but their usefulness in differentiating the source of effusions is limited. [90] [91] The highest WBC levels are usually seen with empyema, with values often >50,000/mm [3] . [64] Differential cell counts may be grouped by the predominant cell type, usually reported as polymorphonuclear cells or mononuclear cells (which include lymphocytes). [8] Typical WBC and differential findings in pleural fluid are summarized in Table 8-6 (Table Not Available) .

Other patterns may include eosinophil counts >10% with blood or air within the pleural space as well as with parasitic and fungal disease. [8] An RBC count >100,000/mm3 suggests trauma, malignancy, or pulmonary infarction. [88] A pleural fluid hematocrit may

be performed on bloody effusions. Values greater than half the peripheral hematocrit should indicate a hemothorax. [8]

Numerous chemical analyses of pleural fluid are available and may help differentiate the causes of effusions. Glucose levels are usually low (<60 mg/dL) in malignancy, rheumatoid pleuritis, empyema, or, occasionally, tuberculosis. [8] Amylase levels >160 Somogyi units suggest pancreatitis, pancreatic malignancy, esophageal rupture, or, occasionally, lung cancer. [93] Creatinine levels elevated above the serum

| TABLE 8-7 -- Classification of Pleural Effusions |
| --- |
| *From Ross DS: Pleural effusion. In Harwood-Nuss AL, Linden CH, Luten RC, et al (eds): The Clinical Practice of Emergency Medicine. JB Lippincott Co, 1990. Reproduced by permission.* |
| (Not Available) |

level may be found in pleural effusions due to obstructive uropathy. [94] [95] Pleural fluid lactate 10 mmol/L above blood lactate suggests a pyogenic pleural effusion. [96] The pH of the pleural fluid may be decreased below 7.30 in cases of malignancy, rheumatoid disease, and, occasionally, tuberculosis. This is also particularly helpful in delineating empyemas and complicated parapneumonic effusions that may need thoracostomy tube drainage. Findings of pH <7.2 to 7.3 are considered significant. [8] [64]

Milky fluids due to thoracic duct disruption from trauma or lymphoma are known as *chylous effusions,* which may be differentiated from chyliform effusions seen in tuberculosis, rheumatoid disease, and trapped lung. [88] This is a most important distinction, because chylothorax may require tube thoracostomy. Triglyceride levels >110 mg/dL and chylomicrons, which stain with Sudan III stain, are seen in chylous effusions. Chyliform effusions have elevated cholesterol levels, may demonstrate cholesterol crystals on microscopic examination, and do not stain with Sudan III stain. The previously mentioned lipid values may also be obtained by lipoprotein electrophoresis. It has also been suggested that cholesterol levels >60 mg/dL may help define an exudate. [97]

If clinical suspicion warrants, further laboratory tests of pleural fluid may provide useful information. Reduced complement levels may be found in pleural effusions due to rheumatoid arthritis and systemic lupus erythematosus. Lupus erythematosus cells may be seen on a Wright stain. Rheumatoid factor titers >1:320 suggest a rheumatoid pleural effusion. Elevated CEA levels may be suggestive of adenocarcinoma. [8]

The presence of bacteria may be identified in Gram stains and anaerobic and aerobic cultures of empyema and parapneumonic effusions. Countercurrent

immunoelectrophoresis may also detect the presence of bacterial antigens in parapneumonic effusions. [8] Stains for acid-fast bacillus and tuberculosis cultures may identify tuberculous pleural effusions. Fungal and mycoplasmal cultures may also be obtaine.

# THORACENTESIS IN PEDIATRIC PATIENTS

## Indications

The indications for performing thoracentesis are much the same in children as in adults: relief of a suspected tension pneumothorax, diagnostic tap of a pleural effusion, and therapeutic drainage of a large symptomatic pleural effusion.

Pneumothorax and tension pneumothorax may develop in children for similar reasons as in adults. In all ages, mechanical ventilation and PEEP increase the risk of developing pneumothorax. During the neonatal period, however, the incidence of pneumothorax seems to increase. [98] It occurs with increasing frequency with fetal distress, difficult deliveries, meconium aspiration, cardiopulmonary resuscitation, hyaline membrane disease (respiratory distress syndrome), pulmonary interstitial emphysema, and phenobarbital sedation of low-birth-weight infants. [99] A second contralateral pneumothorax may occur in neonates on positive-pressure ventilation. [100] In the older child, trauma is a common cause of pneumothorax. Spontaneous pneumothorax also occurs and may be associated with asthma, bronchiolitis, cystic fibrosis, staphylococcal pneumonia, empyema, metastatic carcinoma,

dermatomyositis, Ehlers-Danlos disease, and Marfan syndrome. [101] An increased incidence of tension pneumothorax, which may occasionally occur bilaterally, accompanies cystic fibrosis. [102] In children at any age, pneumothorax can progress to tension pneumothorax, particularly in those being mechanically ventilated and those on PEEP.

Pleural effusions may be encountered in the pediatric age group for most of the same reasons as they occur in adults. Juvenile rheumatoid arthritis and systemic lupus erythematosus may also be causes. [103] Parapneumonic effusions are common causes of pleural effusions and are most often due to pneumococcal infection. Empyema usually occurs because of a staphylococcal infection. [101] [104] In the neonate, spontaneous hemothorax may be due to hemorrhagic disease of the newborn, disseminated intravascular coagulation, arteriovenous malformations, and pleural vascular rupture. [75]

### Diagnosis of Tension Pneumothorax

The newborn child with a tension pneumothorax may present with increasing respiratory difficulty marked by irritability, grunting, tachypnea, intercostal and supraclavicular retractions, and nasal flaring. Cervical crepitus may be present. Cyanosis and cardiovascular collapse and decreased mental status may occur. The findings of a tracheal shift and ipsilateral tympany to percussion may be found but are often not

appreciated in the newborn. A hyperinflated, relatively immobile hemithorax and decreased breath sounds may be seen occasionally but are frequently absent. This absence may be due in part to the ease with which breath sounds are transmitted from the uninvolved side in the neonate. A shift in the apical pulse may be a more reliable sign. [8]

In the older child, a pneumothorax usually causes dyspnea and pleuritic chest pain. A tension pneumothorax may reveal decreased breath sounds, tympany to percussion, and tracheal shift. Tachycardia, tachypnea, agitation, use of accessory muscles, nasal flaring, and cyanosis may be seen. Subcutaneous emphysema and cardiovascular collapse should suggest the progression of a tension pneumothorax.

A pneumothorax is best seen on an upright chest film. In the neonate, a cross-table lateral radiograph may be more useful than a supine chest film. [105] Tension pneumothorax is easily recognized on an upright posteroanterior chest film by the absence of pulmonary markings, shift of the mediastinum, and flattening of the diaphragm. Pneumomediastinum and subcutaneous emphysema may be seen. However, it is appropriate to relieve a tension pneumothorax by needle or catheter aspiration when it is recognized clinically. Awaiting radiographic diagnosis is only indicated when the patient's cardiopulmonary status is relatively stable or when the diagnosis of tension pneumothorax is in doubt. The diagnosis may be confirmed by a rush of air and clinical improvement with decompression.

A bilateral tension pneumothorax may be difficult to diagnose clinically. On a chest film, microcardia, flattened diaphragm, and the bilateral absence of lung markings are seen. In such a case, bilateral chest decompression confirms the diagnosis.

**Diagnosis of Pleural Effusion**

In the pediatric population, pleural effusions may be asymptomatic or may appear with respiratory compromise, pleuritic chest pain, cough, dyspnea, or signs and symptoms of underlying systemic illness, such as fever or weight loss. A pleural friction rub may be heard. Bronchial breath sounds may be heard in the infant. [101] A moderate to large pleural effusion may be recognized on physical examination by the presence of decreased breath sounds, dullness to percussion, and decreased excursions of the ipsilateral hemithorax.

Large pleural effusions may be seen on a standard upright chest film displaying the same findings as in the adult. For small effusions, lateral decubitus films may be necessary. Bilateral decubitus views may help assess the underlying lungs as well as whether the effusion is loculated.

**Treatment**

Treatment is directed toward the underlying cause. Supplemental oxygen may be beneficial. The indications for thoracentesis in children include relief of a tension pneumothorax and diagnostic or therapeutic drainage of a pleural effusion. In cases of

parapneumonic effusion from lobar pneumococcal pneumonia, thoracentesis may be withheld. [101]

**Position**

Immobilization of the child may pose a significant problem because of the child's size as well as the frightened child's inability to comprehend the explanation for the procedure. Gentle and simple explanations are appropriate for older children. Sedation may be helpful when respiratory distress is minimal. Oxygen saturation (see Chapter 6) should be monitored if sedation is used. Children should be held securely by an assistant. It is important to position the child as described for adults to provide the proper access to the insertion site and reliable landmarks. To relieve a tension pneumothorax, a child may be positioned supine on a stretcher. The head may be elevated 30°. For removal of pleural fluid, the child should be seated, leaning against the back of a chair or table in the same manner as indicated for adults. If pillows are used, care must be taken to ensure an adequate airway. For the child who is unable to sit up, the lateral decubitus position may be used. A neonate may be held in the "burping" position by an assistant. [106]

**Insertion Site and Procedure**

The insertion sites for relieving tension pneumothorax and removing pleural fluid are much the same as those recommended for adults. The second or third intercostal space in the midaxillary line is usually recommended for relief of a tension pneumothorax. The fourth or fifth intercostal space in the anterior axillary line is also suggested. [106] A needle or catheter may be inserted using the smaller suggested gauge as recommended for adults. The procedure follows the same technique as that used in adults.

Pleural fluid is best removed from the seventh or eighth intercostal space in the posterior axillary line. In children, the seventh intercostal space, located at the tip of the scapula when the arm is slightly elevated, is a reliable landmark. [107] Confirmation by physical examination and chest film is appropriate. A standard needle, a "butterfly scalp vein" needle, over-the-needle catheter, or a through-the-needle catheter may all be used. Again, the smaller-gauge needle suggested for adults is recommended. The techniques for needle or catheter insertion are the same as those described for adults. Pigtail catheters have been used successfully in children to drain both pneumothoraces and effusions. [33] [34] The Seldinger

technique as described earlier for adults is used for inserting the catheters.

Once a tension pneumothorax is diagnosed, a thoracostomy tube is indicated and should be inserted, even if the patient has experienced temporary relief from needle decompression. A thoracostomy tube should also follow thoracentesis if a hemothorax or empyema is found.

## COMPLICATIONS

The most frequent complication caused by inserting a thoracentesis needle or catheter into the thorax from any approach is the *creation* of a pneumothorax. Although many patients already have a small pneumothorax, it may become larger or even become a tension pneumothorax during the procedure. The mechanisms for this complication are a laceration of the underlying lung, an inadequate coverage of the hub of the needle or catheter after the pleural space is entered, an inadequate drainage system, or an air leak in the drainage system or thoracentesis apparatus. The risk of pneumothorax or tension pneumothorax secondary to lung puncture may be increased with patients who are intubated and on positive-pressure ventilation. Iatrogenic pneumothorax also appears to occur more often when performing therapeutic thoracentesis and when malignancy is present. [86] If a pneumothorax is found on a follow-up chest film, tube thoracostomy may also be indicated, according to the criteria in Chapter 9 . Approximately one third of pneumothoraces induced during thoracentesis require a thoracostomy tube. [86]

Cough is another frequently encountered complication (9% of patients). [86] Although seemingly only a symptomatic problem, it may be associated with the creation of an iatrogenic pneumothorax. It has been suggested that on encountering coughing, one should consider terminating the procedure.

Although rare, unilateral pulmonary edema may occur following thoracentesis. It was initially reported following the use of excessive negative pressures in the evacuation of a pneumothorax. [108] [109] Unilateral pulmonary edema has, likewise, been seen following evacuation of a pleural effusion. [110] The pulmonary dysfunction may be the consequence of local hypoxia in the atelectatic lung, with resultant changes in the basement membrane or loss of surfactant, as well as from excessive pleural negative suction pressure. When performing thoracentesis for evacuation of air, one can minimize these changes by applying a passive underwater seal. Any negative suction pressure should be applied gently and may best be accomplished via controlled pressure drainage systems and tube thoracostomy. When removing large pleural effusions, the incidence of postexpansion pulmonary edema may also be decreased by applying gentle evacuation pressures and by frequent measuring of pleural pressures using a column manometer held below the entry site. It is recommended to cease the evacuation if pressures go below -18 cm $H_2O$. [82] Once pulmonary edema develops, administering oxygen is appropriate for relief of hypoxia. Rarely, PEEP may be needed to correct this complication. A case has been reported in which the hypoxia associated with reexpansion pulmonary edema actually improved following the inadvertent redevelopment of the pneumothorax. [111]

Reexpansion hypotension has also been reported following rapid evacuation of persistant unilateral pneumothoraces of at least 1 week's duration. The hypotension occurred in association with unilateral reexpansion pulmonary edema, a rising hematocrit level, and anuria despite relatively normal pulmonary capillary wedge pressures. Intravascular volume depletion and myocardial depression are the suggested mechanisms. [112] [113]

Transient hypoxia has been noted as a consistent finding after thoracentesis. [114] There

may be a ventilation-perfusion mismatch with perfusion of atelectatic lung or areas of localized pulmonary edema. Although the hypoxia usually is not significant clinically, oxygen administration may be indicated, particularly in the patient with minimal respiratory reserve. Oxygen saturation monitoring (see Chapter 6) may be useful in such patients.

Although hemothorax and hemoperitoneum are uncommon, they represent significant potential complications of thoracentesis. Hemothorax may be due to laceration of the lung and diaphragmatic, intercostal, or internal mammary vessels. Cardiac perforation has been reported following thoracentesis in a pneumonectomized patient. [115] Careful attention to technique, such as avoiding the superior portion of the intercostal space, never puncturing medial to the midclavicular line, and not penetrating too deeply into the thorax during needle insertion, should be practiced. Hemothorax may be diagnosed by the rapid accumulation or reaccumulation of fluid as noted on a post-thoracentesis upright chest film. If this occurs, evacuation through a thoracostomy tube is usually indicated according to the criteria indicated in Chapter 9 . Hemoperitoneum may result from puncture of the spleen or liver through the diaphragm. This may occur when thoracentesis is performed with a low posterior approach during expiration. If laceration of intra-abdominal contents is suspected, close observation is essential. A surgical consultation is usually in order, and an exploratory laparotomy may be indicated. Computed tomography may be helpful as an alternative diagnostic approach for suspected intra-abdominal solid organ injury.

As with all surgical procedures, there is a potential for infection. The risk of infection is estimated at 2%. [8] The risk is kept low with proper attention to patient preparation and sterile technique. In the case of rapid relief of a tension pneumothorax, preparation is minimal; however, any risk of infection is greatly outweighed by the risk of cardiopulmonary collapse from a tension pneumothorax.

Inadvertent shearing of the plastic catheter may occur when a through-the-needle catheter technique is used. This complication is prevented by securing the needle with a needle guard after it has been withdrawn from the chest. In addition, the catheter should not be withdrawn back through the needle at any time. Should a catheter tip be left in the chest, a method of percutaneous retrieval using a bent needle tip under fluoroscopy has been described. [116] Some other technical problems of thoracentesis may be encountered. The most common are "traumatic" taps, which are contaminated by blood (11%), and "dry" taps, in which no fluid or inadequate fluid is obtained (9%). [86] Grogan and associates found fewer pneumothoraces and dry taps when thoracentesis for pleural effusion was guided by ultrasonography. [117] Air embolus can occur if the thoracentesis device is left open to air and if the needle or catheter is inadvertently inserted into a pulmonary or intrathoracic blood vessel. Hypoproteinemia may occur after removal of a large pleural effusion. A thick pleural "peel" may accumulate secondary to inadequate

drainage of a hemothorax or an empyema. This complication is avoided by using tube thoracostomy, rather than thoracentesis, to drain blood or empyema more completely. Pleural "peels" may occasionally require thoracotomy and chest decortication.

# Chapter 9 - Tube Thoracostomy

**Seth W. Wright**

Tube thoracostomy is a commonly performed procedure that is used to evacuate an abnormal collection of air or fluid from the pleural space. Normally, the visceral and parietal pleurae are closely approximated. This potential space between the two layers is occupied by only a thin layer of fluid that acts as a lubricant. The pleural space normally has a subatmospheric pressure secondary to the elastic recoil forces of the lung and chest wall. [1] The addition of air, blood, or other fluids to this space disrupts the normal ventilatory mechanism, producing subjective dyspnea and interference with normal gas exchange. The amount of pulmonary and cardiovascular dysfunction is generally proportional to the volume of the abnormal collection and the rate at which it accumulates. Experimental studies of pneumothorax in animals have demonstrated that respiratory and cardiovascular embarrassment result from multiple mechanisms, including respiratory muscle dysfunction, mechanical interference with ventilation, shunting of pulmonary blood flow, ventilation-perfusion mismatch, and increased resistance to blood flow through the pulmonary vascular bed. The end result is a reduction in stroke volume and systemic oxygen delivery. [2] [3] Data from monitored humans with tension pneumothorax further reveal an elevation of pulmonary arterial, central venous, and pulmonary artery occlusive pressures, along with the development of hypoxemia and mild acidemia. [4]

Tube thoracostomy is indicated for a wide variety of medical and surgical conditions (Table 9-1) . The procedure

| **TABLE 9-1** -- Indications for Tube Thoracostomy |

is widely used in the emergency department for individuals who have sustained penetrating chest trauma during violent crimes or blunt trauma following motor vehicle accidents or falls. Tube thoracostomy also is used frequently in cases of spontaneous and iatrogenic pneumothorax. In the setting of a tension pneumothorax, the procedure may be immediately life-saving.

## BACKGROUND

The treatment of empyema using incision, cautery, and metal tubes was first described by Hippocrates. However, it was not until the 19th century that modern methods for the evacuation of pleural contents were developed. Continuous intercostal drainage with a water seal for the treatment of empyema was described in the English literature in 1872 [5] and a closed system for empyema drainage, shortly thereafter. [6] However, these techniques were not widely performed until 1917, when they were utilized for the treatment of postinfluenzal empyema. [7] In World War II, closed tube drainage was routinely used following chest injury. It is believed that the increased use of these tubes as both initial and definitive treatment for wartime thoracic trauma led to much of the decrease in the mortality rate. [8] During the Civil War, the mortality rate following thoracic trauma was 62.5%; in World War I, 24.6% of chest wounds were fatal; and in

World War II, the mortality rate following chest trauma dropped to 12%. [9]

# INDICATIONS

## Traumatic Pneumothorax, Hemothorax, or Hemopneumothorax

**Pathophysiology**

Pneumothorax and hemopneumothorax are common after blunt or penetrating thoracic trauma. The North American Major Trauma Outcome Study looked at the prevalence of pneumothorax and hemothorax in patients sustaining major trauma. Among 15,047 trauma patients with thoracic injuries (70% from blunt trauma), a pneumothorax was present in 20%, and 25% had a hemothorax. [10] Pneumothorax following blunt chest trauma is usually attributed to lung puncture from a rib fracture. After trauma, a definite rib fracture may not always be evident on radiographs. In the absence of fractures, pneumothorax is believed to result from rupture of an alveolus secondary to abrupt increases in intrathoracic and intra-alveolar pressures against a closed glottis. The air leak may be self-limited, or a ball valve mechanism may lead to a tension pneumothorax (see later discussion).

Air in the pleural space following blunt trauma is not always secondary to primary lung injury. Esophageal rupture and injuries to the tracheobronchial tree also may be responsible for pneumothorax and are often manifested by persistent air leaks; occasionally food particles in the thoracostomy tube drainage may be noted. Penetrating injuries result in simple pneumothorax by allowing air to enter the chest, either through a persistent chest wall defect or by direct injury to underlying lung.

Hemothorax may result from bleeding from the heart,

lungs, great vessels or their branches, intercostal arteries or veins, mediastinal veins, diaphragm, chest wall vessels, fractured ribs, or torn pulmonary adhesions. Bleeding from the lung parenchyma is usually self-limited because of the relatively low-pressure vascular supply of the lung and the high concentration of tissue thromboplastins. In addition, reexpansion of the collapsed lung generally tamponades the low-pressure bleeding sites. Partially severed intercostal arteries bleed particularly briskly, because all but the first two come directly from the aorta. In addition, a partially lacerated internal mammary artery rarely ceases bleeding without surgical intervention.

**Diagnosis**

**Physical examination.**

Alert patients with a pneumothorax, hemothorax, or hemopneumothorax may complain of chest pain, usually pleuritic in character, and shortness of breath. Pneumothorax alone may be manifested by increased resonance to percussion, decreased tactile fremitus, decreased or absent breath sounds, or subcutaneous (SQ) emphysema. As a general rule, air in the SQ tissues (SQ emphysema) originates from an internal

structure, such as lung, bronchi, or esophagus, although it may represent air introduced from the ambient environment following a penetrating thoracic wound. On occasion, SQ emphysema following blunt trauma may not be associated with a pneumothorax. With an isolated hemothorax, breath sounds will be decreased as well, but the percussion note is dull. A succussion splash has been described when air and fluid are both present. It is important to note that *physical examination is often misleading, and many pneumothoraces may go undetected by physical examination alone*.

Hemothorax alone also may be difficult to detect. Patients can rapidly lose 30 to 40% of their blood volume into the pleural space, with little resistance from the compliant lung. They may then present primarily with signs of shock. The presence of shock in a patient with a chest injury should also raise the question of pericardial tamponade, which may not be manifested by distended neck veins in the hypovolemic patient. Evidence of mediastinal shift or compression (distended neck veins, shifted trachea) may represent massive blood or fluid accumulation or, more likely, tension pneumothorax. In contrast, a small hemothorax (<400 mL) may produce few clinical findings. Physical findings of a hemothorax include dullness to percussion or loss of breath sounds at the lung base.

**Radiographic diagnosis.**

A standard, 6-foot posteroanterior (PA) upright chest radiograph is the diagnostic procedure of choice for hemothorax or pneumothorax. However, radiographic studies may be limited to a portable supine anteroposterior (AP) view in the critically ill patient. A pneumothorax is diagnosed more readily on the *expiratory* radiograph, because the lung collapses further. A pneumothorax may also be accentuated with a lateral decubitus film (unaffected side down, injured side up). One can often obtain a sitting (portable) 6-foot PA film in patients (who may require some assistance) by having them sit up and "hug" the x-ray plate to their chest. The machine is placed at the standard distance behind the patient. This view more closely approximates standard technique and allows a better evaluation of mediastinal size. Otherwise, AP films should be taken with the patient sitting in as erect a position as possible.

Computed tomography (CT) scans of the thorax and upper abdomen may be superior to plain radiographs for the detection of a small hemothorax or pneumothorax. Garramone and coworkers [11] reported the unexpected finding of a pneumothorax in 26 of 457 patients undergoing abdominal CT scanning for the evaluation of trauma. None were apparent on prior x-rays of the chest. Poole and colleagues [12] compared plain films with chest CT scans in blunt chest trauma patients. The CT scan detected significantly more pneumothoraces (23% vs 14%) and more pleural effusions (34% vs 14%) than did plain films. However, the findings seen only on CT scans were invariably small and unassociated with complications.

When one is interpreting a supine chest film, it is important to compare the relative densities of both lung fields. On a supine chest radiograph, as much as 1000 mL of blood may be manifested only as a *slight homogeneous increase in the density of one hemithorax*. Up to 500 mL of blood may be required to produce blunting of the costophrenic angle on an upright film. Subpulmonic collections can resemble an elevated hemidiaphragm. Lateral decubitus films may be required to demonstrate either

of these findings. *If an air-fluid level is seen* (straight line to the top of the fluid collection), as opposed to a fluid meniscus, *a pneumothorax must also be present* (Fig. 9-1) .

The size of the pneumothorax can be estimated by the method outlined in Figure 9-2 . [13] The area of the collapsed lung is subtracted from the area of the involved hemithorax. The area of the collapsed lung can be calculated in the figure using the area of a rectangle drawn to include the extreme superior ( *a*), lateral ( *b*), and inferior ( *c*) margins of the collapsed lung and the center of the mediastinum ( *d*). This number is then subtracted from the area of a rectangle encompassing the entire affected hemithorax, measured from the inferior border of the first rib ( *A*), the inner border of the midlateral chest wall ( *B*), the tip of the costophrenic angle ( *C*), and the center of the mediastinum ( *D*). The difference between the area of the hemithorax and the area of the collapsed lung is divided by the area of the hemithorax to yield the percentage of the pneumothorax.

Alternatively, the size of a pneumothorax can be estimated by calculating the average interpleural distance as described in Figure 9-3 (Figure Not Available) . [14] The average interpleural distance is the mean of the maximal apical interpleural distance and the interpleural distances of the upper and lower lung fields. The average interpleural distance is then correlated with the percentage of the pneumothorax size by means of the nomogram in Figure 9-4 (Figure Not Available) .

A simpler way of monitoring the size of the pneumothorax involves measuring from the lateral lung margin to the lateral chest wall on full inspiration. It is important to have some easily reproducible means of repeatedly recording the size of a pneumothorax, particularly if the patient is to be examined by different physicians and management is to be based on serial measurements of pneumothorax size.

**Figure 9-3** (Figure Not Available) Calculation of percent pneumothorax using the average interpleural distance method. The base of the lung is not seen in the posteroanterior (PA) view. The total height of the PA view is assumed to be the same as that shown on the lateral view. *(From Rhea JT, DeLuca SA, Greene RE: Determining the size of pneumothorax in the upright patient. Radiology 144:733, 1982. Reproduced with permission.)*

**Treatment**

In a patient in extremis with evidence of major thoracic trauma (SQ emphysema, palpable rib fractures, flail chest), no further diagnostic studies need be undertaken. Needle aspiration may confirm the diagnosis but can be misleading or may even cause a pneumothorax. If a tension pneumothorax is suspected, needle aspiration may be a temporary solution, but subsequent tube thoracostomy is indicated on the suspected side of injury.

Tube thoracostomy allows egress of the fluid or air and provides a means of continuous drainage and monitoring of the pleural space. Further drainage can be quantified, and the need for other intervention can thus be assessed. Observation of the drainage and collection devices allows for the diagnosis of persistent air leak or other problems that

may require additional treatment.

Not all patients with a pneumothorax require tube thoracostomy. Small pneumothoraces and hemothoraces (<400 mL) have been treated successfully with observation alone if the patient is stable, relatively asymptomatic, otherwise healthy, and not likely to require positive-pressure ventilation. [15] Resolution occurs over 2 to 3 weeks. [16] [17] Northfield has suggested that supplemental oxygen will increase the rate of pleural air absorption several-fold, [18] and such additional

**Figure 9-4** (Figure Not Available) Nomogram for the prediction of pneumothorax size from an average interpleural distance (see text). The intrapleural distance is measured in centimeters from the outer edge of the collapsed lung to the inner aspect of the chest wall (i.e., parietal pleura to visceral pleura). *(From Rhea JT, DeLuca SA, Greene RE: Determining the size of pneumothorax in the upright patient. Radiology 144:733, 1982. Reproduced with permission.)*

therapy should be considered. The placement of a chest tube in stable patients with a small pneumothorax is based on clinical assessment of the potential benefits and risks associated with the individual case. Patients with larger or more symptomatic traumatic hemothorax, pneumothorax, or hemopneumothoraces should have a thoracostomy tube placed.

A tube may be placed "prophylactically" in a patient with evidence of a penetrating injury to the chest, even without demonstrable intrathoracic injury, if anesthesia and positive-pressure ventilation are required or if the patient will be transported a long distance for definitive care of other injuries. Such patients are at high risk for developing a tension pneumothorax when subjected to positive airway pressures. They may also develop a simple or tension pneumothorax during transport when diagnostic adjuncts are suboptimal or definitive treatment may be difficult or impossible.

With the increased use of CT scans for evaluation of thoracic and abdominal trauma, it is clear that many patients with previously unrecognized small pneumothoraces have safely undergone general anesthesia with positive-pressure ventilation without developing a clinically evident pneumothorax. [11] [12] Therefore, whether all patients with a small pneumothorax (i.e., evident only on CT scan) secondary to trauma require a "prophylactic" chest tube when undergoing positive-pressure ventilation is currently controversial. Garramone and coworkers suggest that routine chest tube placement can be avoided if the pneumothorax is small and there are no associated rib fractures. [11] If a chest tube is not placed in a patient with a small, CT-evident pneumothorax and positive-pressure ventilation is administered, close observation for signs of a tension pneumothorax is mandatory.

A recent animal study disputes an old assumption that blood in the chest may tamponade a briskly bleeding vessel and that pleural drainage should be delayed until after volume resuscitation. [19] Indeed, hypoxia and hypercapnia may result if pleural drainage is not instituted quickly. However, early institution of blood replacement is recommended in patients with massive hemothorax (>2000 mL), since massive hemothoraces are often associated with ongoing hemorrhage. Autotransfusion using a commercial device for the collection, filtration, anticoagulation, and autotransfusion of blood obtained by tube thoracostomy (see Chapter 28) is indicated in instances of

massive hemothorax.

Many patients (72 to 82%) with traumatic hemothorax can have their injuries managed successfully by tube thoracostomy and volume replacement alone. [20] [21] [22] In the remaining patients, immediate or delayed elective thoracotomy may be required. There is disagreement among different researchers concerning the indications for surgery. Table 9-2 provides a summary of surgical indications.

**Open Pneumothorax**

Open pneumothorax ("sucking chest wound"; Fig. 9-5) most commonly results from shotgun or combat injuries that result in a loss of chest wall integrity. Such wounds can produce markedly deficient gas exchange and cardiovascular function when the negative intrapleural pressure is replaced with atmospheric pressure. If the chest wall defect is larger in cross-sectional area than the trachea, air will move preferentially through the chest wall with diaphragmatic excursions, and no ventilation will occur. With smaller defects,

a tension pneumothorax (see subsequent discussion) may develop. Clinically, a chest wall defect and SQ emphysema are seen in a patient with marked respiratory distress.

Prehospital treatment involves the application of a (preferably sterile) dressing to act as a one-way (flap) valve, allowing air to exit the pleural space while blocking reentry. In the field, anything (e.g., a palm, plastic wrap, or gauze) can be used. The patient is instructed to perform the Valsalva maneuver after deep inspiration or to cough just as the dressing is placed. Ideally, a sterile dressing of petrolatum-impregnated gauze extending 6 to 8 cm beyond the wound in all directions is used. This underlying dressing should be covered by gauze dressings and secured on three sides only. An airtight dressing could predispose to tension pneumothorax in the presence of a continued intrapleural air leak. This dressing may be sealed after tube thoracostomy through a separate site is performed to allow continued evacuation of air or fluid. The presence of the open wound is an indication for operative debridement and closure of the chest wall defect with continued tube drainage of the pleural space.

## Spontaneous Pneumothorax

### Pathophysiology

Spontaneous pneumothorax (Fig. 9-6) can be divided into primary and secondary spontaneous pneumothorax. [23] Primary spontaneous pneumothorax results from the rupture of a subpleural bleb in a patient who is otherwise without underlying intrathoracic disease. The male-to-female ratio is 6:1, and the typical patient is 20 to 40 years of age and is tall and thin. Less than 10% of primary pneumothoraces occur with exercise. [17] Large case series have documented that spontaneous pneumothorax is primarily a disease of cigarette smokers. [16] [17] A Swedish study [24] has demonstrated that smoking increases the risk of spontaneous pneumothorax 9-fold in men and 22-fold in women. They determined that the life-span risk of developing a spontaneous pneumothorax for heavy smokers is approximately 12%, compared

with a risk of only 1 in 1000 in people who have never smoked. In the United States, the age-adjusted yearly incidence of primary spontaneous pneumothorax is 7.4 per 100,000 males and 1.2 per 100,000 females. [25]

Patients with secondary spontaneous pneumothorax have underlying lung or pleural disease as the cause of the pneumothorax. The most common predisposing factor is emphysema. [23] Other associated potential etiologic factors include chronic bronchitis,

asthma, tuberculosis, pneumonia, bronchiectasis, atelectasis, pulmonary fibrosis, lymphoma, and various connective tissue diseases such as scleroderma or eosinophilic granuloma. Tuberous sclerosis, rupture of a hydatid cyst, pulmonary infarction, foreign body, and alpha1 -antitrypsin deficiency have all been implicated. Neoplasm is a consideration in older patients. Recurrent pneumothoraces attributed to pleural diaphragmatic endometriosis (i.e., catamenial pneumothoraces) occur in some women at the time of menstruation. [26] Patients with acquired immunodeficiency syndrome and *Pneumocystis carinii* pneumonia also have been found to be at increased risk for spontaneous pneumothorax. [27]

The rupture of an emphysematous bleb, an alveolar septum, or the bronchial wall causes air to flow freely into the pleural space. The majority of cases occur when the patients are at rest, and 70% of affected individuals seek medical attention within 24 hours of onset. Case series have reported that 0 to 11% of cases are bilateral. [28] [29] The symptoms correlate with the amount of lung collapse, the mobility of the mediastinum, the amount of respiratory reserve, the presence of underlying disease, and the degree of compression of the rest of the lung. A spontaneous pneumothorax may progress to a tension pneumothorax, although such progression is unusual.

**Diagnosis**

Almost all patients with a spontaneous pneumothorax (95%) complain of chest or shoulder pain (or, rarely, back or abdominal pain) that is usually sudden in onset, sharp, pleuritic, and cutting. Tightness may be described. Sixty percent have dyspnea in addition to these symptoms, and 12% have a mild cough. [16] [30] Breathlessness and anxiety are more common in older patients, and morbidity and mortality are increased in patients with underlying disease. [17] Various degrees of respiratory distress may be manifested. SQ emphysema rarely occurs. Decreased breath sounds, decreased tactile fremitus, and hyperresonance to percussion may be noted in an uncomplicated spontaneous pneumothorax, although the physical examination may reveal no abnormalities if the pneumothorax is small.

The diagnosis is made on a standard upright PA chest film. Small pneumothoraces are best seen by radiography with the patient in full expiration. During expiration, the volume of air in the pleural space remains the same, but the expiratory decrease in the volume of the collapsed lung on the affected side increases the apparent relative size of the pneumothorax. A lateral film helps rule out complications and may help define the etiology when the pneumothorax is secondary to some other intrathoracic pathology. In pediatric

patients or in those who are uncooperative for other reasons, radiographs in both decubitus positions may successfully demonstrate a small pneumothorax. If the patient is placed in the lateral decubitus position with the affected side up, air will collect in the uppermost portion of the pleural space, and the pneumothorax may be more perceptible.

In the patient with chest pain, pneumothorax must be differentiated from myocardial infarction, dissecting aneurysm, pericarditis, pneumonia, pneumomediastinum,

pulmonary embolus, spontaneous esophageal rupture, perforated peptic ulcer, and biliary or renal colic. Radiographically, giant bullae or lung cysts may mimic a pneumothorax, and these must be carefully differentiated, usually by obtaining a decubitus view.

**Treatment**

The treatment varies with the age of the patient, the symptoms, the degree of respiratory compromise, the bilaterality, the need for general anesthesia, the size of the pneumothorax, and whether the current episode represents a recurrence. *From a purely physiologic viewpoint, all patients with a pneumothorax do not automatically require pleural space aspiration.* However, exactly when to treat becomes a clinical judgment issue, and compliance, the need for close follow-up, or other mitigating circumstances may be such that placement of a chest tube is the safest and most expedient course. Otherwise healthy, asymptomatic, reliable patients with small pneumothoraces (<10% or <1 cm collapse laterally) may be treated by observation alone. As previously noted, supplemental oxygen may hasten the resolution of a pneumothorax, and its use should be considered. [18] A period of observation (with the length depending on the amount of time the pneumothorax has been present) is recommended to ensure that the pneumothorax is not expanding. Reexpansion is estimated to occur at 1.25% of lung volume daily. [13] Affected patients who are released home following a period of emergency department observation must be instructed to return immediately if symptoms increase, to minimize their activities, and to have follow-up chest films to document resolution.

Needle or catheter aspiration of a pneumothorax has been advocated by some and has had a variable degree of success (see later discussion). Traditional therapy for a spontaneous pneumothorax consists of tube thoracostomy and water seal drainage with or without suction. The tube evacuates the intrapleural air, prevents further accumulation, and allows monitoring for persistent air leaks. The local irritation produced by the tube is believed to aid in scar formation and in preventing recurrence. The tube is left in place for 24 hours after all evidence of continued air leak has disappeared.

A number of investigators have reported successful outpatient management of chest tubes in about 75% of their patients with spontaneous pneumothorax. [31] [32] [33] Stable patients are selected; these individuals should be free of significant underlying disease or persistent air leaks and should have satisfactory lung reexpansion after 1 to 12 hours of observation in the emergency department (ED). They are sent home with a flutter (Heimlich) valve attached and are seen 3 to 4 days later for tube removal if complete reexpansion is maintained.

Surgical treatment (usually thoracotomy with abrasion of pleural surfaces) is advocated at the time of the first or second recurrence. [33] [34] Patients who have had one pneumothorax have a 30 to 50% chance of ipsilateral recurrence within 1 to 2 years. [33] After a second spontaneous pneumothorax, the probability of a third rises to 50 to 80%. [33] [35] Surgery may be recommended on the occasion of a patient's first pneumothorax in a number of situations: life-threatening tension pneumothorax, massive air leaks with

incomplete reexpansion, an air leak persisting 4 to 5 days after a second intercostal tube has been placed, associated hemothorax with complications, cases of identifiable bullous disease, and failure of easy reexpansion in patients with cystic fibrosis.

## Tension Pneumothorax

### Etiology

Tension pneumothorax (Fig. 9-7) may be a complication of both spontaneous pneumothorax and traumatic hemopneumothorax. Rarely, a pneumothorax that has been stable for a number of days will rapidly develop tension. Fractures of the trachea or the bronchi, the presence of an occlusive dressing over an open pneumothorax, or a ruptured esophagus also may result in tension pneumothorax. The risk is markedly increased in patients with chest trauma who are undergoing positive-pressure ventilation. Because of this, a patient with penetrating thoracic injury (even without immediate evidence of intrathoracic bleeding or air) may be a candidate for a "prophylactic" chest tube placed before surgery. A "tension hemothorax" does not occur in the absence of massive fluid replacement, because the volume of blood required to produce a shift of mediastinal structures requires nearly total exsanguination into the chest. Rarely, a malignant pleural effusion will cause a tension hydrothorax. [36]

### Pathophysiology

Classically, a pulmonary parenchymal or bronchial tear creates a ball valve mechanism. The increased endobronchial diameter and intrathoracic negative pressure during inspiration allow air to pass into the pleural space. The decrease in bronchial diameter and the relatively elevated intrathoracic pressure during expiration cause the leak to close. This mechanism traps increasing amounts of air in the pleural space with each respiratory cycle. As intrapleural pressure rises, venous return to the right heart declines, and cardiac output drops. The mediastinum shifts toward the uninvolved side, mechanically interfering with right atrial filling. Ventilation of both the involved lung and the opposite lung is compromised, and hypoxemia, acidosis, or both result from ventilation-perfusion inequalities. Tension pneumothorax may develop at any time after injury, during resuscitation, or with cardiopulmonary resuscitation (CPR). It should be considered as a possible cause for deterioration in any susceptible patient, particularly if positive-pressure ventilation is being used.

### Diagnosis

Clinically, patients with tension pneumothorax may present with or rapidly develop restlessness, dyspnea, agitation, or cyanosis. Hypotension, tachypnea, tachycardia, nasal flaring, and retractions may occur. Pulsus paradoxus may be evident. There is hyperresonance to percussion and decreased breath sounds on the affected side. Obvious chest trauma, rib fractures, or SQ emphysema should alert one to the possibility of tension pneumothorax. The trachea and the cardiac apex are displaced toward the uninvolved side. Neck veins may be distended but can be flat in the hypovolemic patient. The prominent, fixed, and overinflated hemithorax may be obvious

when the semi-upright patient is inspected from the head or the foot of the bed. Increased airway resistance in an intubated patient (one of the first signs of a tension pneumothorax) may be manifested by increased difficulty in manual ventilation or increased ventilatory pressures when a volume-cycled respirator is used. Although the clinical scenario generally does not permit the luxury of a chest radiograph, the findings of a depressed hemidiaphragm and lung collapse on the affected side with a shift of the mediastinum to the opposite side is classic.

Pericardial tamponade figures strongly in the differential diagnosis and should be considered in the trauma patient when mediastinal shift, hyperresonance, and decreased breath sounds are not prominent clinical features or when needle aspiration of the hemithorax fails to bring prompt relief.

**Treatment**

If the patient is in extremis and the diagnosis is suspected clinically, needle aspiration of the involved side should be undertaken without further delay (see Chapter 8) . Even if no facilities are available for chest tube placement, a large needle inserted into the chest to convert a tension pneumothorax to an open pneumothorax can be life-saving. A 14-ga needle is commonly placed in the second anterior intercostal space but is effective anywhere in the pleural space. A temporary flutter valve may be fashioned from the fingers of a rubber surgical glove until definitive treatment is available. The definitive treatment of a tension pneumothorax is tube thoracostomy.

## Other Indications

**Occult Traumatic Pneumothorax**

In many institutions CT of the abdomen is the procedure of choice for the diagnosis of intra-abdominal injuries following blunt trauma. Abdominal CT routinely includes the lower aspect of the thorax, and small pneumothoraces are easily visualized. Occult traumatic pneumothorax is defined as a pneumothorax that is not evident on a conventional chest radiograph, but is visible on CT. The management of these small pneumothoraces has been controversial, with some advocating immediate tube thoracostomy [37] and others in favor of expectant management in selected patients. [11] [38] One prospective randomized study found that patients with an occult pneumothorax who require positive-pressure ventilation are at risk for progression of the pneumothorax and development of tension pneumothorax. [39] In patients not requiring positive-pressure ventilation, expectant management may be appropriate if the patient is hemodynamically stable. [11] [12] In these patients, close observation and interval radiography is mandatory, and a qualified physician must be immediately available to place a chest tube, if needed. [38]

**Pneumothorax Associated with IV Drug Use**

Pneumothorax has been described following the inhalation of drugs, usually marijuana or cocaine. The barotrauma that follows recreational drug inhalation is likely caused by

the prolonged Valsalva maneuver used to increase the effect of the drug. [40] A common complication seen in IV drug users is a pneumothorax resulting from injecting into the central venous circulation. These "pocket shooters" typically have no peripheral venous access because of sclerosis of their veins. The "pocket shot" involves the central or middle approach to the internal jugular vein and a pneumothorax is a common complication due to the proximity of the apex of the lung. [41] The patient will present with the typical signs and symptoms of a spontaneous pneumothorax. Treatment of these patients is discussed below.

**Drainage of Recurrent Pleural Effusions**

Initially, most pleural effusions can be managed by thoracentesis (see Chapter 8) , but recurrent effusions may require tube thoracostomy.

**Empyema**

Empyema was one of the first recorded indications for continuous intercostal drainage in adults [6] and children [5] and remains a prominent one today.

**Chylothorax**

Chylothorax can be a rare complication of thoracic trauma or central line placement with resultant thoracic duct injury. It may be seen with penetrating injury or a fall from a height. Chyle collects extrapleurally, and 2 to 10 days may elapse before it enters the pleural cavity. Initially the few clinical manifestations may be masked by other injuries. As fluid accumulates in large amounts, dyspnea and the physical findings of a pleural effusion become prominent. Thoracentesis reveals a milky white liquid with a high lymphocyte count, 4 to 5 gm/dL of protein, and a high fat content. Repeated thoracentesis or tube thoracostomy is combined with bedrest and parenteral alimentation until the volume of chyle declines. [42]

**Postoperative Thoracotomy**

Chest tubes are nearly always placed under direct vision when open thoracotomy is performed.

**Iatrogenic Pneumothorax**

The leading causes of iatrogenic pneumothorax are transthoracic needle aspiration, subclavian vein catheterization, and thoracentesis. [43] Patients with a minimal pneumothorax have been managed successfully with observation and supplemental oxygen. Those with a small pneumothorax have been treated variably (e.g., catheter placement, pneumothorax aspiration and Heimlich valve use vs small chest tube placement). Those with large or recurrent pneumothoraces or those undergoing positive-pressure ventilation generally receive formal tube thoracostomy. Despars and coworkers [44] found that 66% of patients with an iatrogenic pneumothorax were treated with a chest tube for a mean duration of 4.7 days. Nine of 65 (14%) patients required a

second chest tube, and 2 deaths were attributed to an iatrogenic pneumothorax in their series.

## CONTRAINDICATIONS

A list of contraindications is provided in Table 9-3 . There are probably no absolute contraindications in the compromised patient who requires the procedure, although some relative contraindications exist. Multiple pleural adhesions, emphysematous blebs, and scarring should mandate caution in a stable patient. It is important to note that a giant emphysematous bleb or bulla in adults and congenital lobar emphysema in infants may be extremely difficult to differentiate from a pneumothorax on chest films. A second or third spontaneous pneumothorax in a stable patient may be an

indication to proceed directly to surgery instead of attempting another tube thoracostomy. A patient requiring immediate open thoracotomy (e.g., in the case of cardiac arrest after penetrating trauma) may not benefit from chest tube placement. The presence of a massive hemothorax usually requires rapid blood or crystalloid replacement with or without immediate surgery. The setting of bleeding dyscrasias before clotting factor replacement may be a relative contraindication.

## EQUIPMENT

### Instruments

The instruments required for performing tube thoracostomy by the method detailed below are listed in Table 9-4 . Prepared "trays" are available in hospitals and often contain many more instruments than are required or described here. In addition to the instruments, a number of other materials are needed; these are listed in Table 9-5 . All the necessary items should be assembled and tested before the start of the procedure. If the tape is torn as desired, the solutions are poured, the packages are opened, and a checklist (mental or written) is reviewed before beginning, the procedure will go much more smoothly.

| **TABLE 9-5** -- Other Materials Required for Tube Thoracostomy |
|---|
| Local anesthetic |
| Antiseptic solution |
| Arm restraints (padded) |
| Petrolatum-impregnated gauze |

| |
|---|
| Tincture of benzoin |
| Adhesive tape--cloth-backed |
| Chest tubes |
| No. 28 to 36 Fr for adults |
| No. 16, 20, 24 Fr for children |
| Clear, sterile plastic tubing in 6-foot lengths, 1/2-inch diameter |
| Hard plastic serrated connectors |
| Drainage apparatus with sterile water for water seal |
| Y connectors |

**Chest Tubes**

The size, shape, and characteristics of tubes used for thoracostomy vary considerably. The most commonly used devices are clear plastic, straight tubes with a series of holes at one end. They have a radiopaque strip that is commonly interrupted by the last fenestration. Sizes used for adults vary from No. 12 to 42 Fr. Most authorities believe that No. 20 to 32 Fr tubes are adequate for a pneumothorax alone, although small catheters (8 Fr) have been suggested, especially if the patient is to be treated and released. Larger tubes (a minimum of 36 Fr) are best when blood or pus is to be drained. It is a mistake to attempt to drain a hemothorax with a small chest tube. For

pediatric patients, No. 16, 20, and 24 Fr tubes are adequate.

# PROCEDURE

The ideal procedure performed under ideal circumstances is described. The degree of urgency, as determined by the patient's condition and the available resources, will dictate how closely to the ideal a particular chest tube insertion will come. Under the best circumstances, the diagnosis should be established before the procedure and the appropriate radiographs taken. The preferred films are upright PA and lateral chest radiographs. The nature and necessity of the procedure should be explained to the patient as completely as possible, and it is preferable to obtain and document informed consent.

**Tube Location**

The classic approach has been to place tubes anteriorly in the second intercostal space, midclavicular line (usually 2 inches from the lateral border of the sternum) for pneumothorax alone, and dependently in the midaxillary or posterior axillary line, and then direct them posteriorly for fluid removal (Fig. 9-8) . *In an emergency, a tube placed anywhere in the pleural space should be adequate.* The anterior second intercostal space is nearly always mentioned as a location for tube placement but in practice is less often used. Disadvantages include the need to dissect through several inches of muscle mass and the resulting unsightly and highly visible scar.

It is probably reasonable to avoid the second intercostal space entirely and use only midaxillary line placement for all clinical indications. It is cosmetically preferable and better tolerated and is believed to result in increased pleural involvement and scarring. If the tube is placed slightly anterior to the midaxillary line, the patients may lie on their backs more comfortably. Hegarty randomly placed tubes in the second intercostal space, midclavicular line, or the fifth intercostal space, midaxillary line, in 131 cases of pneumothorax or combined hemopneumothorax. He found that the time to removal of the tube was not influenced by location, regardless of whether air, blood, or both, was being drained. [45] Another study looked at 156 randomly placed chest tubes and found no unsatisfactory results with pneumothorax, regardless of tube position. [46] Logically, as the collapsed lung expands and the parietal and visceral pleurae become more tightly opposed, either air or fluid will follow the path of least resistance and enter a functioning drainage

**Figure 9-8** Standard sites for tube thoracostomy. *A,* The second intercostal space, midclavicular line. *B,* The fourth or fifth intercostal space, midaxillary line. Most clinicians prefer midaxillary line placement for all chest tubes, regardless of pathology. Note that placing the tube too far posteriorly will not allow the patient to lie down comfortably.

tube, regardless of the tube's location. Although some clots may remain in the pleural space, blood that is drained from the chest cavity has no demonstrable fibrinogen. [47] Therefore, a tube anywhere in the pleural space should adequately drain a hemothorax

of unclotted blood, as long as there are no adhesions.

Specific recommendations for lateral placement have varied from anterior to posterior axillary lines and from the fourth to the eighth intercostal space. If time permits and the physician who will subsequently be caring for the patient can be consulted, the physician's preference should be followed. For all clinical indications for routine placement in the emergency department, the fourth or fifth intercostal space slightly anterior to the midaxillary line is suggested for chest tube placement. This is roughly at the level of the nipple or the inferior scapular border in most patients. Placement of the tube posterior to the midaxillary line may result in significant patient discomfort when the patient reclines. The tube is directed posteriorly and toward the apex of the lung. This has proved satisfactory for drainage of either fluid or air. If fluid continues to accumulate, a second tube may be placed in the posterior axillary line at the same interspace or one interspace lower.

The location of the diaphragm varies with the position of the patient and can rise quite high when the patient is supine. The phase of respiration and other associated injuries (diaphragmatic hernia, abdominal distention) also can alter its position. The most reliable means of preventing inadvertent damage to lung or abdominal viscera is a thorough digital exploration of the pleura before tube insertion. If the patient breathes during this procedure, the location of the diaphragm can often be verified, and intrapleural placement can be ensured.

## Tube Insertion

### Patient Preparation

For axillary insertions, the patient is ideally placed with the head of the bed elevated 30° to 60° (Fig. 9-9) . Inserting a

**Figure 9-9** To insert a chest tube, the patient is placed semi-erect with the ipsilateral shoulder abducted. Supplemental oxygen is suggested, as is the liberal use of appropriate parenteral analgesia and/or sedation.

chest tube while the patient is lying flat increases the chances of injury to the diaphragm, the spleen, or the liver and presents a more difficult operating position for the practitioner. When the patient is lying down, the diaphragm may rise as high as the third intercostal space. The arm on the affected side is placed over the patient's head and restrained in that position with wide strips of adhesive tape or by other means. The other arm can be restrained comfortably at the patient's side. (Even in the conscious and seemingly cooperative patient, judicious use of comfortable restraints before painful or frightening procedures often allows more rapid and efficient procedural completion.) For anterior midclavicular line placements, the patient's arms may be placed at the sides.

After identifying the area of tube placement, the surrounding skin should be shaved if necessary. The area is sterilized with a povidone-iodine solution or another suitable

antiseptic and draped with sterile towels. Nasal oxygen may be helpful for the patient with subjective dyspnea.

**Anesthesia**

*A local anesthetic should be used generously*; careful anesthesia can render the procedure nearly painless (Fig. 9-10) (Figure Not Available) . Often 1% buffered lidocaine (Xylocaine) with epinephrine (1:100,000) is used. The maximum lidocaine dose of 5 mg/kg should not be exceeded. A skin wheal should be raised with a 25- to 27-ga short (½- to 5/8-inch) needle in the area of the skin incision. Many physicians advocate locating the skin wound one intercostal space below the one through which the tube will pass. The "tunneling" up and over the next rib that is required if this is to be done is believed to provide a better seal against air leaks both while the tube is in place and during and after its removal (Fig. 9-11) (Figure Not Available) . A larger (23-ga, 1½ inch) needle is used to infiltrate the SQ tissues, the muscle, the periosteum, and the parietal pleura in the areas through which the tube will pass. The sterile syringe should be kept readily available, as additional anesthesia is often required. A common error is inadequate local anesthesia. Intercostal nerve (rib) blocks above and below the incision and insertion rib spaces are also helpful. The anesthetic needle and syringe should be used to aspirate the pleural cavity in the area of insertion (Fig. 9-12) (Figure Not Available) . If air or fluid is not obtained and the patient's condition is stable, the diagnostic evaluation may need to be repeated or the insertion site changed. This simple and extremely useful technique to verify the location and the character of the intrapleural accumulation is often forgotten.

Appropriate IV analgesia and sedation should be administered to the hemodynamically stable patient. The careful use of conscious sedation during the procedure is strongly advocated when appropriate (see Chapter 35) . Supplemental oxygen should be considered, if only for patient reassurance. Once the tube is in place, anesthetic may be administered through the chest tube. [48] One approach for stable patients is to administer 10 mL of 0.5% bupivacaine through the chest tube while the patient is lying on the contralateral side. After 5 minutes without drainage of the thorax, standard gravity or vacuum drainage is reinitiated. Additional parenteral analgesic agents may be administered as the patient's condition warrants.

**Insertion**

One measures the length of the tube to be inserted by holding it near the chest wall. *It is a common mistake to advance chest tubes too far or not far enough.* Estimation of the desired placement depth will minimize tube adjustments and repeated radiographs. The distance from the incision site to the apex of the lung is estimated, and a clamp is placed on the tube at the point at which it should enter the chest wall. This position must be proximal enough from the last drainage hole to ensure that all holes are within the pleural space. The beveled (extrathoracic) end of the tube is often cut

**Figure 9-10** (Figure Not Available) Insertion of a chest tube can be relatively painless with proper infiltration of the skin and pleura with local anesthetic. The liberal use of *buffered* 1% lidocaine with epinephrine (maximum lidocaine dose, 5 mg/kg) is recommended. *(Redrawn from Hughes WT, Buescher*

*ES: Pediatric Procedures. 2nd ed. Philadelphia, WB Saunders, 1980, p 234.)*

**Figure 9-11** (Figure Not Available) The skin wound is made one intercostal space below the space through which the tube will pass *(A)*. By spreading tissue with scissors or a Kelly clamp *(B)*, blunt dissection is carried subcutaneously and into the pleural space *(C)*. A common error in technique is to attempt to insert a large chest tube through a skin incision that is too small. *(Redrawn from Hughes WT, Buescher ES: Pediatric Procedures. 2nd ed. Philadelphia, WB Saunders, 1980, p 237.)*

squarely at this time so that it better fits the commonly available connectors.

A generous 2- to 4-cm transverse skin incision is made through the skin and the SQ tissues directly over the rib located one interspace beneath the rib the tube will pass over. It is a common error to attempt to place a chest tube through an incision of inadequate size. This incision is extended by blunt dissection with a Kelly clamp to the fascia overlying the intercostal muscles. *A scalpel is needed only to make the skin incision.* Care must be taken to avoid the intercostal vessels and the nerve located on the inferior margin of each rib (Fig. 9-13) (Figure Not Available) . A large Kelly clamp is used to tunnel superiorly through the SQ tissues over the rib above, pushing forward with the closed points and then spreading and pulling back with the points spread (see Fig. 9-11) (Figure Not Available) . The closed points of the heavy clamp are then pushed with some force through the muscles, and the parietal pleura immediately overlying the rib and the pleural cavity is entered.

**Figure 9-12** (Figure Not Available) Use of the anesthetic needle to puncture the parietal pleura and establish the presence of blood or air in the pleural space. This procedure not only is diagnostic, but also may be a temporary therapeutic maneuver in a patient with tension pneumothorax. *(Redrawn from Richards V: Tube thoracostomy. J Fam Pract 6:631, 1978.)*

A twisting or drilling motion will enhance pleural penetration. A rush of air or fluid should occur at this point, and the patient may feel discomfort. If pleural fluid is under enough pressure, it may be expelled with considerable force and cover the unwary (and subsequently embarrassed) practitioner with blood or pus. Therefore, appropriate gown, glove, mask, and goggle precautions should be observed by the practitioner. The tips of the clamp, still within the pleural cavity, are spread widely and withdrawn (Fig. 9-14) (Figure Not Available) . The clinician must be certain to make an adequate opening in the pleura.

Next is one of the most important parts of the procedure: *the insertion of a gloved finger into the chest to verify that*

**Figure 9-13** (Figure Not Available) Location of the intercostal neurovascular bundle, running inferiorly and slightly medial to the rib. *(From Millikan JS, Moore EE, Steiner E: Complications of tube thoracostomy for acute trauma. Am J Surg 140:739, 1980.)*

**Figure 9-14** (Figure Not Available) One accomplishes blunt dissection by forcing the closed points of the clamp forward and then spreading the tips and pulling back with the points spread. A rush of air or fluid signifies penetration into the pleural space. *(From Bricker DL: Safe, effective tube thoracostomy. ER Reports 2:49, 1981.)*

*the pleura has been entered and that pleural adhesions are absent.* The finger should

sweep completely around the hole in the chest wall. Dense adhesions may mandate an alternative site for tube placement. The finger is left in the pleural space, and the tube is then grasped with the curved clamp, with the tube tip protruding from the jaws (Fig. 9-15) . (Another technique is to pass one jaw of the clamp inside the tube through a distal fenestration.) *With the finger in the chest cavity as a guide*, the tip is placed into the pleural space (Fig. 9-16) (Figure Not Available) . The finger is used to verify intrapleural

**Figure 9-15** The tube is grasped with the curved clamp, with the tube tip protruding from the jaws.

**Figure 9-16** (Figure Not Available) Using the finger as a guide to ensure entry into the pleural cavity, one places the tip of the tube into the pleural cavity. It is surprisingly easy to advance a chest tube subcutaneously, entirely missing the pleural space. *(From Millikan JS, Moore EE, Steiner E: Complications of tube thoracostomy for acute trauma. Am J Surg 140:739, 1980.)*

placement of the chest tube. The curve in the clamp is used to guide the tip superiorly and posteriorly. The clamp is released, and the tube is pushed superiorly, medially, and posteriorly until the marker clamp that was previously attached to measure the insertion distance touches the chest wall. All the holes in the chest tube must be within the pleural space. A common error, especially in obese patients, is to fail to advance the chest tube far enough into the pleural space, leaving the drainage holes either in the SQ tissues or outside the skin.

Alternatively, the tube may be advanced until pain is felt or resistance is met, and then pulled back 2 to 3 cm. It is surprisingly easy to misdirect the chest tube, even though the pleural space has been opened. Subcutaneous placement is a frequent complication, and dissection of tissue planes in the chest wall by an advancing chest tube can simulate entry into the chest cavity (Fig. 9-17) . Therefore, after placement, a finger is passed along the tube to verify entry into the thorax. Entry into the thoracic cavity also is suggested by the appearance of condensation on the inside of the tube coincident with respiratory movements, the audible movement of air through the tube during respiration, the free flow of blood or fluid, and the ability of the operator to rotate the tube freely after insertion. The tube is attached to the previously assembled water seal or suction setup by means of a sterile serrated connector before the clamp is released. Asking the patient to cough and thereafter observing bubbles in the water seal device is a good way to check system patency.

**Securing the Tube**

Before elaborate steps are taken to secure the tube, the clinician should be certain that the chest tube position is

**Figure 9-17** Subcutaneous (SQ) placement of a chest tube ( *arrows*) is surprisingly easy, as the tube can dissect through tissue planes with relative ease. The incorrect placement was not appreciated until the radiograph was taken. If the tube is directed posteriorly, an anteroposterior radiograph of the chest would erroneously "confirm" intrapleural placement despite the tube being SQ throughout its entire course.

verified on a chest film. There are as many ways of fastening a chest tube in place as there are physicians who place the device. More important than the individual technique chosen is the need to communicate the method used effectively to the person who will be caring for the patient, particularly the one who will be removing the tube. Some clinicians prefer wire, but I advocate sturdy silk sutures. Nylon sutures are difficult to tie tightly and are not recommended.

A reasonable approach is as follows: An 0 or 1-0 silk suture on a cutting needle is used. (Flimsy suture material, such as size 3-0 or finer, should be avoided.) The first suture is placed next to the tube to close the lateral margin of the skin incision and is tied firmly (Fig. 9-18) . The ends of this "stay" suture are left long and are then tied repeatedly around the chest tube and knotted securely to hold it in place. The sutures must be tied tightly enough to indent the chest tube slightly and thereby avoid slippage. A horizontal mattress suture is then placed around the tube approximately 1 cm across the incision on either side of the tube (i.e., cephalad and caudad to the tube) (Fig. 9-19) . This will be used to close the incision after the tube is removed. No knots are tied initially, but the skin should be pulled snugly together and held with a surgeon's knot (double-throw knot). The loose ends are repeatedly wound tightly around the chest tube as it enters the skin, with occasional repeated surgeon's knots tied tightly enough to indent the tube gently. The final knot is a bow, which should clearly identify the suture as *one not to be cut* when removing the chest tube.

An occlusive dressing of petrolatum-impregnated gauze should be placed where the tube enters the skin. Overlying this should be two or more gauze pads with a Y-shaped cut from the middle of one side to the center. These are oriented at 90° to each other (Fig. 9-20) . The shaved skin and the

**Figure 9-18** A "stay" suture is first placed next to the tube to close the skin incision. *A,* The knot is tied securely and the ends, which will subsequently be wrapped around the chest tube, are left long. *B,* The ends of the suture are wound twice about the tube tightly enough to indent the tube slightly and are tied securely.

tube may be coated with tincture of benzoin and wide (8- to 9-cm) cloth adhesive tape used to hold the tube more securely in place. Two strips of tape applied with an "elephant-ear" technique at 90° to each other provide an excellent method of securing the tube in place (Fig. 9-21) . The tape is torn so that one end is split into three pieces extending halfway to the center. The two outside pieces are placed on the skin on either side of the tube site, and the center piece is wrapped tightly around the tube. This is repeated with a second piece of tape, which is torn similarly and placed at 90° to the first. A third simple piece of tape may be used elsewhere on the chest to prevent the tube from being pulled loose accidentally. The connections are then securely taped.

**Confirmation of Tube Placement**

Repeat PA radiographs (and occasionally a lateral radiograph) must be taken to confirm tube placement and to document the degree of resolution. In a stable patient, it is often

better to obtain the postprocedure films with a less elaborate temporary dressing in place, in case tube repositioning is required. It is important to note that a simple pneumothorax should be completely reexpanded within a few minutes of continual suction. If the film taken after chest tube insertion shows that the lung is still collapsed, the clinician should consider three possibilities: (1) The tube may be in the wrong place, or the most proximal hole is outside the chest cavity. (This is the most easily corrected problem.) (2) A persistent air leak, usually from a large bronchus or the trachea, may be delaying expansion. (3) Plugging of a main bronchus with blood, mucus, or aspirated material may be delaying resolution of the pneumothorax.

## Drainage System

Physicians who place chest tubes infrequently or who do not participate in the ongoing care of patients who have undergone this procedure may have little familiarity with the physiology and mechanics of chest tube drainage systems. Life-threatening complications may arise from improper use of these devices, however, and the physician must be knowledgeable about the salient features of the system.

With the availability of modern closed drainage systems, the classic glass bottle collection system is rather cumbersome and largely antiquated. Nevertheless, the principles of the various drainage systems are discussed here. The simplest drainage device is a flutter (Heimlich) valve (commonly used only for pneumothorax) attached to the end of the chest tube itself (Fig. 9-22) . Such valves allow one-way flow of air from the chest but collapse to prevent air from passing back into the chest. Normal respiration, assisted by coughing, gradually removes the excess air from the pleural space, and the lung reexpands to fill the thoracic cage. The one-way Heimlich valve does not require a suction source when its purpose is the drainage of a pneumothorax. Therefore, it can be used in the treatment of outpatients. This valve is not generally used in conjunction with a closed suction-driven collection system to drain a hemothorax, because backflow is not a problem during continuous suction.

The simplest device to remove small amounts of either fluid or air is the underwater seal (single-bottle) device (Fig. 9-23) . The chest tube is connected to a second plastic tube,be extends 2 to 4 cm below the surface of the sterile water placed in the drainage bottle. The water provides a seal against the entrance of further air into the chest. The water also acts as a one-way valve. The intrathoracic pressure need only be greater than the depth of immersion of the tip of the drainage tube in the collection bottle to cause the intrathoracic air or fluid to exit into the bottle. This is easily accomplished with simple coughing.

For air to enter back into the pleural space through the chest tube, the patient must generate enough negative intrathoracic pressure to pull the water in the collection bottle up to the height of the chest. Normal inspiration is not forceful enough to do this if the bottle is kept on the floor. Normal fluctuation in the height of the fluid level in the long tube during respiration provides proof that free communication exists with the pleural space and that the tube is functioning normally. An absence of respiratory fluctuation or a decrease in the drainage implies blockage or, if the tube has been in for a sufficiently long period, full expansion of the lung and obliteration of the pleural space. The two

situations (blockage and full expansion) should be distinguishable by clinical and radiographic means.

On the other hand, an increase in respiratory fluctuation may imply an increased inspiratory effort owing to airway obstruction or atelectasis. If blocked, the tube and collecting tubing may be changed, "milked," or "stripped" to dislodge clots. *Milking* refers to forcing air or fluid back into the chest by pinching or clamping the tube distally and, with the other hand, compressing the tube and forcing the contents proximally. This can dislodge a blocking intrathoracic clot and can obviate the need for tube replacement when radiographic or clinical examination suggests incomplete expansion or drainage. *Stripping* involves proximal pinching or clamping and progressive distal compression followed by release of the proximal aspect. This allows the tube to spring open. The sudden increase in negative pressure may extract clots and fluid from a more proximal location. These procedures are more effective with soft latex tubing than with clear plastic tubes. However, routine use of milking and stripping should be avoided because of the high pressures generated during these procedures. [49]

Persistent bubbling in the tube during both expiration and inspiration implies an air leak, the most common source of which is the drainage system connections. These should be taped thoroughly and rechecked frequently. Another source of leakage may be failure to get the last opening in the chest tube inside the chest wall so that ambient air is sucked into the exposed hole. When the tube is appropriately placed into the thorax, air leaks through the chest wall are uncommon. One can best prevent such leakage at the skin incision site by initially tunneling up one interspace and by using effective suture technique and a petrolatum-impregnated gauze dressing.

The drainage bottle must always remain dependent, because gravity contributes a great deal to the proper drainage of the pleural space. Elevating the bottle above the chest can cause fluid to reenter the chest and can increase the probability of infection. The length of the tubing must be carefully controlled so that dependent loops of fluid do not form. Such loops of accumulated liquid must be displaced before more air or fluid can pass. The amount of positive intrapleural pressure required for air to pass through a dependent loop of fluid is greater than the vertical elevation of the fluid in the loop (Fig. 9-24) (Figure Not Available) . If the fluid loop becomes high enough (15 to 25 cm $H_2O$), egress of air may be blocked to a degree sufficient to cause a tension pneumothorax. [50] Similarly, as fluid accumulates in the water seal, the immersed tip of the tube must be raised so that it stays 2 to 4 cm below the water surface. Otherwise, a similarly progressive increase in intrathoracic pressure will be required to continue emptying the pleural space.

Sometimes a second trap, or collecting bottle, is placed proximal to the water seal (Fig. 9-25) . This has the advantage of keeping the level of fluid in the water seal bottle constant and allows for better measurement of collected drainage. A disadvantage is that air can enter the chest tube from the first bottle with accidental disconnection of any of the tubes or with a significant increase in negative intrapleural pressure. The dead space provided by the dry trap can produce an air lock effect and can lead to to-and-fro pressure changes with ventilation without effective drainage. More commonly, when a 2-bottle system is used, the second bottle is connected to suction. The amount of

suction in tube 1 is regulated not by the pressure reading on the wall suction valve, but by the depth of water in the second bottle above tube 3 and by the depth of tube 1 (Fig. 9-26) . When suction exceeds the depth of the water in bottle 2, air enters from the top of the third tube to prevent further increases. The internal diameter of the various tubes (especially tube 3) also contributes to the amount of suction that can be created.

The more complex the system, the more problems that can occur. Evaporation occurs quickly, and fluid levels must be maintained to keep pressures from steadily decreasing. Vigorous bubbling in the first bottle may cause foam to rise and to be suctioned into the second, either breaking the water seal or changing the pressure regulation. A few drops of a chemical agent (caprylic alcohol) can be used in bottle 1 to prevent this. As the first bottle fills with fluid, the effective suction decreases because of an increase in hydrostatic pressure at the bottom of tube 1. Although a 2-bottle system (water seal plus suction regulator) is adequate for nearly all emergency department applications, [51] a number of

**Figure 9-26** A 2-bottle system for applying regulated suction to the pleural space. The height of the column of water in bottle 2 regulates the amount of suction applied, independent of the pressure on the suction valve.

self-contained setups that avoid the bulky bottle system are commercially available.

Some add a third bottle for fluid collection (Fig. 9-27) (Figure Not Available) . Commercially available chest drainage systems that mimic the 3-bottle system are currently used by most hospitals. These units are plastic, lightweight, compact, easily transported, and easily assembled. Currently available models (Fig. 9-28) (Figure Not Available) collect up to 2500 mL of fluid, allow easy regulation of suction, and can be used for autotransfusion. Because glass bottles are cumbersome and time consuming to assemble, EDs are strongly urged to use the convenient, disposable chest drainage collection systems.

Occlusive clamping of chest tubes should be performed only with great trepidation and physician supervision, particularly in the first 24 hours after the tubes are placed. Clamping with a persistent intrathoracic air leak or fluid accumulation may lead rapidly to a tension pneumo- or hemothorax. Clamping is appropriate only to change the underwater seal bottle rapidly. Patients with chest tubes in place are best transported without clamping--on water seal only, with the bottle placed well below chest level.

**Role of Suction**

Suction is recommended at least initially in all patients with chest tubes placed for either pneumothorax or hemothorax. [35] [52] Ideally, a suction machine must have high flow (up to 20 L/min) and a regulated constant suction (0 to 60 cm $H_2O$). The continuous bubbling and the lack of respiratory variation with suction can mask the presence of an air leak. With extensive bleeding, excessive suction may actually increase the rate of blood loss, particularly when the bleeding is from a relatively low-pressure pulmonary vessel. Intermittent clamping or water seal use may be preferred. With a massive air

leak, excess suction may cause respiratory distress by removing inspired air before alveolar gas exchange can occur. Suction may be useful for rapid initial expansion and drainage. Because of the added complexity and complications, suction should be replaced by simple underwater seal drainage as long as expansion and drainage are satisfactory and no persistent air leak exists. When suction is applied, a pressure of 20 cm $H_2O$ is normally used.

**Prophylactic Antibiotics**

The routine use of prophylactic antibiotics in patients requiring tube thoracostomy is controversial. However, patients with associated injuries who are at high risk for infection (e.g., those who have undergone a nonsterile procedure or those with open fractures, a perforated viscus, or an esophageal injury) are always given antibiotics. Whether patients with isolated chest trauma or spontaneous pneumothorax require antibiotic prophylaxis has yet to be definitively determined. In one prospective, randomized, double-blind study of 75 patients with penetrating chest injuries, 2.6% of those treated with clindamycin developed empyema, compared with 16.2% of patients given placebo. [53] In another study of the use of cefoxitin in patients with either blunt or penetrating chest trauma, there was 1 infectious complication among 30 patients (3.3%); the chest infection rate in patients who did not receive antibiotics was 29%. [54] Another randomized double-blind study comparing cefazolin with placebo demonstrated a lower rate of sepsis and positive sputum cultures. [55]

**Figure 9-27** (Figure Not Available) A 3-bottle system with fluid trap bottle, water seal, and adjustable vent tube. *(From Miller KS, Sahn SA: Chest tubes: Indications, technique, management and complications. Chest 91:258, 1987.)*

However, in a series of 80 patients with penetrating chest injuries, 0 of 40 patients treated with doxycycline and only 1 of 40 who were not given antibiotics demonstrated infections. [56] A meta-analysis concluded that there was a statistically significant effect favoring antibiotic prophylaxis

**Figure 9-28** (Figure Not Available) Diagram of a modern commercially available chest drainage system. Included is a 2500-mL fluid collection chamber, a suction control device, an air leak indicator, and a fluid sampling port. A separate attachment is available for autotransfusion. *(Courtesy of Davol, Inc, a division of CR Bard, Cranston, RI.)*

after tube thoracostomy. [57] Probably more important than the use of antibiotic prophylaxis is ensuring, when time permits, that strict aseptic technique is followed when the tube is initially placed.

If antibiotics are used, the first dose is given as soon as possible, preferably before the tube is inserted, and continued until the tube is removed. The chosen antibiotic should cover *Staphylococcus aureus,* as this is the most common organism causing empyema, but gram-negative bacteria coverage is also desirable. A first- or second-generation cephalosporin is probably a good choice, because these agents have a broad spectrum of activity and easily pass into the pleural space. Nichols and colleagues [58] noted a reduction in infectious complications from 10.7 to 1.6% in patients requiring chest tube insertion predominantly for penetrating chest trauma with the prophylactic use of the

once-daily cephalosporin cefonicid. Others have recommended clindamycin, cefoxitin, cefazolin, cefamandole, or doxycycline. It appears reasonable to administer prophylactic antibiotics when the chest tube is placed in an emergency situation and the potential for infection is greater because of possible contamination, especially in cases of penetrating chest trauma. Stable patients who receive a chest tube in controlled and elective situations (especially in the setting of a spontaneous or iatrogenic pneumothorax) probably do not require antibiotic prophylaxis.

## Tube Removal

Recommendations vary, but chest tubes should generally be removed when there has been no drainage of fluid or air for a minimum of 24 hours, when respiratory variations in the water seal have ceased, and when high-quality radiographs reveal satisfactory resolution of the initial pathology. Because of pleural irritation, small amounts of serous fluid (<200 mL/day) may continue to drain without contraindicating removal.

To remove a chest tube, the patient should be placed in a semi-upright position, and the dressings should be removed. Sedation or restraints may be helpful. The area should be sterilized and draped, and sterile technique should be followed. The only instruments required are sterile basins, heavy scissors to cut the suture, dressing materials, and instruments to tie the previously placed pursestring suture or to place a new one. Facilities and equipment should be

available to reinsert a new chest tube promptly if it should become necessary. The suture holding the tube to the skin should be removed from the tube, and the pursestring suture that was previously placed should be loosened and readied for tying. A second (gloved) assistant is helpful. The tube should be clamped, and the connecting tubing should be removed. A petrolatum- or antibiotic-impregnated gauze dressing should be prepared. The patient should inhale fully and perform a mild Valsalva maneuver. The tube is removed in one swift motion while the patient holds the breath. Two fingers hold the skin edges shut, and the pursestring suture is tied. The occlusive dressing is placed and taped securely. A period of observation (minimum, 2 to 6 hours) is recommended if the patient is to be sent home, with a chest film obtained at the end of that time. Any increase in symptoms requires prompt reevaluation. After 48 hours, the dressing may be removed and the wound managed as any sutured skin wound would be.

## Other Techniques

### Trocar Insertion

Percutaneous introduction of a chest tube with a trocar was a common practice in the past. This technique has been largely abandoned because of the risk of major complications, such as damage to lung and solid organs. [59] Most authorities currently condemn the use of a trocar for the placement of a large-bore chest tube. [52] [60] The above described blunt technique is the favored method. Although use of the trocar to forcibly enter the chest is condemned, some clinicians still use it to carefully guide (not force) the tube through an existing thoracic wall opening made by the blunt dissection

technique.

Whereas the use of trocars for initial entry of the chest during insertion of large-bore tubes is fraught with danger, new minicatheter systems that combine the trocar approach with a guide wire dilator system appear promising for management of pneumothoraces. These catheter systems are used in the fashion described below.

**Minicatheter Insertion**

**Indications and contraindications.**

A less invasive alternative to traditional tube thoracostomy for patients with a simple uncomplicated pneumothorax is treatment with minicatheter placement for pneumothorax aspiration. Advantages of this technique include the ease of catheter insertion, decreased patient discomfort, less scarring, increased patient mobility, and decreased cost. In addition, after successful reexpansion of the lung, selected patients may be treated as outpatients. Patients with iatrogenic pneumothorax (e.g., that which occurs after central line placement, lung biopsy, or bronchoscopy), those who have IV drug use-induced pneumothoraces, victims of minor chest trauma, and patients with spontaneous pneumothoraces are potential candidates for catheter aspiration of the pneumothorax. Patients with multiple rib fractures, tension pneumothorax, hemothorax, hemodynamic instability, or serious associated injuries requiring surgery should receive conventional tube thoracostomy. Patients with underlying lung pathology, such as pneumonia, congestive heart failure, asthma, or emphysema, are generally not candidates for minicatheter use.

Minicatheter aspiration is particularly effective for patients with a needle-induced (i.e., iatrogenic or IV drug "pocket shooters") pneumothorax. In these patients, success rates ranging from 75 to 93% have been reported. [41] [61] [62] [63] This technique is somewhat less effective in patients with a spontaneous pneumothorax [63] [64] because of the continued air leak from ruptured blebs. A recent randomized study compared aspiration with traditional tube thoracostomy in patients with a spontaneous pneumothorax. [65] Aspiration was effective 80% of the time, and the patients had decreased pain and a shorter hospital stay. The authors concluded that aspiration is a simple and safe procedure and is the treatment of choice in patients with normal lungs and a spontaneous pneumothorax, irrespective of size.

**Equipment.**

A No. 14 through-the-needle Intracath, a 14-ga IV catheter, or an 8.5 Fr Arrow trauma catheter inserted using the Seldinger (guide wire) technique may suffice for simple aspiration. However, these catheters are designed for fluid administration and have only a single distal hole that can easily become obstructed or adhere to the pleura when suction is applied. Therefore, it is suggested that a catheter designed specifically for the purpose be used, particularly if it is to be left in place for a prolonged period of time. The commercially available catheters have multiple distal side ports and are made of a soft,

flexible, thrombosis-resistant, radiopaque material such as polyurethane.

Available commercial systems include the 8 Fr guide wire system by Cook (CCASP-FORD-110485, Cook Catheter, Bloomington, Ind), and 8 Fr over-the-needle systems by Arrow (AK-01500, Arrow International, Reading, Pa) and Argyle (8888-567032, Argyle, Sherwood Medical, St Louis). A 14 Fr introducer (Introstat, Hart Medical, Clearwater, Fla) and 12 Fr polyvinyl chloride chest tube system (Argyle, Sherwood Medical) has been used as a compromise between the smaller catheters and a full-sized chest tube. [32]

**Procedure.**

Placement of a catheter into the pleural space is relatively simple. The patient is placed in a semi-upright position and sterile preparation is performed with povidone-iodine solution at either the fourth or fifth intercostal space at the anterior axillary line or the second or third intercostal space at the midclavicular line; either site is acceptable. Anesthesia with generous local infiltration of lidocaine, as described for standard tube thoracostomy, is administered before insertion of the catheter. The exact technique depends on the type of equipment to be used.

**Guide wire (Seldinger) technique.**

A thin-walled 16-ga needle is advanced cephalad over the top of the rib at a 60° angle (Fig. 9-29) . When the pleural space is entered (identified by the aspiration of air into the syringe), a guide wire is inserted and the needle removed. A small incision is made in the skin with a No. 11 blade, and the minicatheter with an introducer is threaded over the guide wire into the pleural space. The wire is then removed, and a three-way stopcock is attached along with a 60-mL syringe. Air is then aspirated until resistance is felt. Often a surprising amount of air can be removed. Occasionally air cannot be aspirated because the catheter is kinked or blocked with soft tissue. If no air is obtained, the clinician should place the patient in the full upright position, have the patient cough or take a deep breath, or withdraw the catheter slightly. This often results in successful aspiration. When no additional air can be aspirated, a chest radiograph is obtained to document full expansion of the lung. If residual pneumothorax is present, an attempt at further aspiration is made.

**Over-the-needle technique.**

First, a small incision is made in the skin with a No. 11 blade (Fig. 9-30) . Then the needle tip, with constant suction on the attached syringe, is advanced into the pleural space. Proper placement is confirmed by the free flow of air into the syringe. The catheter is then advanced over the rib into the pleural space, ensuring that all of the side ports are within the pleural space. The catheter is then connected to a three-way stopcock, and air is aspirated with a syringe as described above.

A protocol using catheter aspiration as the first step in treating simple pneumothoraces (Fig. 9-31) (Figure Not Available) has been described. [66] Patients with successful

aspiration are observed in the emergency department for 4 hours, and if a repeat radiograph shows no reaccumulation of air, the catheter is removed. After 2 more hours of observation, another chest radiograph is obtained, and the patient is released if there is no recurrent pneumothorax. A Heimlich valve is attached to the catheter if a patient has more than a 10% residual apical pneumothorax. The valve is placed on suction only if this does not result in full expansion. Patients with continued residual pneumothorax then receive a conventional tube thoracostomy.

Using this protocol, Vallee and coworkers [66] reported a 59% success rate with simple aspiration in 35 patients with a total of 37 pneumothoraces. An additional 27% responded to the use of a Heimlich valve with or without suction. Only five patients (14%) required a tube thoracostomy; two of these were patients who initially responded to catheter aspiration but returned with a recurrent pneumothorax on follow-up visits. This protocol appears to be useful in patients with selected simple pneumothoraces, but further study is warranted. In particular, outpatient therapy consisting of a small catheter with an attached Heimlich valve may be the best strategy in selected patients with a spontaneous pneumothorax. [67]

### Simple Thoracostomy

When an emergent condition exists with hemodynamic decompensation, the clinician may consider simple thoracostomy without immediate chest tube placement. Deakin and colleagues reported using this technique in out-of-hospital patients needing decompression of a pneumothorax or hemothorax while under positive-pressure ventilation. [68] They used the standard approach for chest tube placement (i.e., incision, curved forceps penetration of the pleura, and digital exploration of the thorax to rule out adhesions and confirm intrathoracic location). Incisions were covered with plain sterile gauze. A chest tube was placed at a later time if radiographs revealed incomplete expansion of the pneumothorax or incomplete drainage of a hemothorax. They observed no obstruction of the incision by a thrombus. *It is imperative that patients treated in this manner receive positive-pressure ventilation.* Otherwise, the thoracostomy incision may give rise to an increasing pneumothorax as negative inspiratory pleural pressures develop.

## PNEUMOTHORAX IN PEDIATRIC PATIENTS

Pneumothorax occurs more commonly during the neonatal period than at any other time of life. When chest radiographs are taken of all newborns in large series, the incidence of pneumothorax is about 1 to 2%. The incidence does not seem to change when normal (term) vaginally delivered newborns are compared with premature newborns or those delivered by cesarean section. The incidence of symptomatic pneumothorax in newborn infants, however, is consistently only 0.05 to 0.07%. Among newborns with pneumothorax, several studies report twice as many males as females. Some studies report more instances of right-sided collapse. Ten to 20% of cases are bilateral. [69]

It should be noted that lobar emphysema in a newborn may cause severe respiratory symptoms shortly after birth (Fig. 9-32) (Figure Not Available) . The physical examination may detect decreased breath sounds in a hemithorax and even evidence of

mediastinal shift. Lobar emphysema often looks like a tension pneumothorax radiographically, and the unwary physician may rush to insert a chest tube. The treatment in this case is surgical removal of the diseased lobe, and a chest tube may worsen the clinical condition.

## Pathophysiology

There seem to be two groups of newborns who develop pneumothorax. The first are term or post-term neonates with a history of fetal distress; difficult delivery; need for resuscitation; or aspiration of meconium, amniotic fluid, or blood. These infants tend to become symptomatic within the first 2 hours of life and generally fare quite well. The mechanism in this group is believed to be an excess intra-alveolar pressure generated at birth. With the first breath, the transpulmonary pressure increases from 40 to as much as 100 cm $H_2O$. Compression of the chest during vaginal delivery places the diaphragm and the muscles of respiration at a marked mechanical advantage. With mechanical obstruction of some alveoli or bronchioles, as can occur with aspiration, the intense transpulmonary pressure is transmitted to the normally aerated alveoli, which can overdistend and rupture. Mechanical ventilation, end-expiratory pressure, and resuscitative efforts can also precipitate alveolar rupture.

The second group of newborns with pneumothorax are those who have underlying pulmonary disease (most notably, respiratory distress syndrome) or congenital abnormalities. These infants commonly develop a pneumothorax in the second day of life, often while being treated with positive airway pressures. The prognosis in these cases is much worse. [69] [70]

## Presentation and Diagnosis

The physical examination of the newborn with pneumothorax can yield findings ranging from no abnormalities whatsoever to complete cardiovascular collapse. Grunting respirations and tachypnea (to a respiratory rate as high as 120 breaths/min) are often seen. Retractions or nasal flaring can be seen, and crepitus in the neck may be present. Cyanosis may be present or may occur only with crying or feeding. Irritability, restlessness, apneic periods, bradycardia, or tachycardia may be the only manifestation. Distention and tympany of the affected side may be found. A decrease in breath sounds is difficult to appreciate in the newborn. With tension pneumothorax, the cardiac impulse and the trachea may be shifted away from the affected side.

The definitive diagnosis is made with high-quality radiographs taken in both the AP and the horizontal beam (cross-table) lateral projections. Small pneumothoraces may be seen only on the lateral view, as the air collects at the top of the thoracic cavity. Bilateral tension pneumothorax can appear as microcardia, without any mediastinal shift. Further radiologic studies may be needed to differentiate this condition from lung cysts, lobar emphysema, and skin folds.

Transillumination of the chest with a high-intensity fiberoptic light source has been used with great success to detect and follow pneumothorax and pneumomediastinum in newborns. [71] It has been noted that abrupt changes in transthoracic impedance in

infants on respiratory monitors have been related to the appearance of pneumothorax. [72] Such changes should initiate prompt reevaluation of the patient's respiratory status.

**Treatment and Indications for Thoracostomy**

In general, tube thoracostomy is the treatment of choice once a symptomatic pneumothorax is detected in infants. When signs of tension pneumothorax are present, immediate aspiration with a plastic catheter over-the-needle device is recommended (see Chapter 8) . Small pneumothoraces (<20% of the hemithorax) in relatively asymptomatic infants (i.e., those who are without other problems and who do not require positive airway pressures) can be monitored merely with close observation.

Repeated films or transillumination and frequent monitoring of vital signs and arterial blood gases are indicated. Breathing 100% oxygen is believed to hasten reabsorption by as much as six-fold. [70] However, the risks of retrolental fibroplasia and pulmonary oxygen toxicity must be carefully assessed when considering oxygen therapy.

When evacuation of the pleural space is elected, needle aspiration using a 50-mL syringe, an 18-ga catheter over-theneedle device, and a three-way stopcock may be attempted once. This may suffice in patients without a continued air leak, although the risk of lung puncture is considerable.

**Thoracostomy Technique**

The technique of tube thoracostomy in pediatric patients varies little from that already described. Small, commercially available thoracostomy tubes can be used. No. 8 to 10 Fr catheters are used in premature infants, and No. 10 to 12 Fr catheters are used in larger newborns. Blunt dissection minimizes the complications of lung puncture, hemorrhage, and traumatic fistula formation, which are seen more often with trocar insertion.

Various tube locations have been proposed. One study compared lateral placement (fourth to fifth intercostal space, anterior axillary line) and superior placement (first to third intercostal space, midclavicular line) of 149 chest tubes for their effectiveness in evacuating pneumothorax. The most important factor was the eventual location of the tube rather than the site of insertion. Anterior tubes were effective 96% of the time, whereas only 42% of the tubes directed posteriorly functioned satisfactorily. [73]

Placement in the third intercostal space, midaxillary line, with the tip directed under the sternum appears to be a good compromise. [72] Care must be taken to avoid the nipple, which can be difficult to identify in the premature infant. Water seal with 10 to 20 cm $H_2O$ for suction is usually recommended until reexpansion occurs and the absence of continued air leakage is verified.

Smaller collecting bottles are recommended to measure drainage more accurately. A miniature water seal apparatus using a 50-mL multiple-use saline bottle, standard IV tubing, and one long and one short needle has been described (Fig. 9-33) (Figure Not

Available) .

## COMPLICATIONS

As with any surgical procedure, complications can and will occur (Table 9-6) . Local infection at the site of insertion is common and may reflect the often hurried performance of this procedure in the emergency setting. Osteomyelitis has been reported in settings in which tubes have been kept in place for a long time. Empyema is uncommon, because tube thoracostomy remains a useful treatment for this problem. Documented cases of empyema developed in only 1.2 to 3.0% of patients after tube thoracostomy. [75] [76] Empyema tends to occur in patients with a loculated effusion and in those who are inadequately drained. Pneumonia and atelectasis are attributed to a decrease in coughing and failure to clear secretions because of pain. As for any postoperative patient, early ambulation and vigorous pulmonary toilet are indicated. The easiest way to provide analgesia for patients with postprocedural pain is to administer parenteral analgesia, but intrapleural bupivacaine after chest trauma or spontaneous pneumothorax is effective in reducing pain and may be useful for reducing pain-related complications. [48] [77] Pain relief extending to several hours has been observed if 20 mL of 0.25% bupivacaine is inserted into the pleural cavity via the chest tube, with pleural drainage interrupted for 5 to 10 minutes and the patient lying supine. [48] Up to 40 mL of 0.25% bupivacaine administered intrapleurally will result in blood levels well below the toxic range. [78]

A local hematoma may occasionally develop at the incision site but may be prevented by careful dissection. Intercostal arteries or veins may be lacerated at the time of tube insertion. These lacerations can be minimized if sharp dissection is carried only to the fascia and the tube is carefully placed just above the rib. The tube may adequately tamponade such bleeding, but if tamponade is insufficient, the incision may have to be extended to expose or ligate the bleeding vessel. If a lacerated intercostal artery does not stop bleeding, the clinician may attempt to insert a Foley catheter into the incision, inflate the balloon, and withdraw the catheter to tamponade the vessel. Anterior chest wall tube placement carried to the midline may result in internal mammary artery laceration. This is notoriously difficult to control and may require thoracotomy. Great vessel injury is uncommon.

A 1% incidence of technical complications (visceral perforation) was documented in a series of 447 patients who

underwent tube thoracostomy for trauma. [59] Another case series reported a 1.8% rate of errors related to placement of the chest tube in 164 patients in their series. [75] Damage to the lung parenchyma or the intrapulmonary vessels can occur readily. This is more common with the trocar insertion technique, which currently has been largely abandoned in favor of blunt dissection. The use of digital exploration of the pleura to exclude or free adhesions is mandatory before tube placement. Careful attention to anatomy, with recognition of exactly how high the diaphragm may rise (especially if the abdomen is filled with blood), can minimize injuries to the diaphragm or the intra-abdominal organs.

Reexpansion pulmonary edema is a potentially fatal complication of thoracentesis or tube thoracostomy. [79] Pulmonary edema was reported in 14% of patients with spontaneous pneumothorax in one series, [80] although the prevalence reported in other series is much lower. [28] Pulmonary edema, usually ipsilateral, can appear as soon as 1 to 2 hours after lung reexpansion. Edema commonly occurs when collapse has been

present for longer than 72 hours and when 1000 mL or more of pleural fluid is removed. Suction seems to worsen the edema. The exact pathogenesis of reexpansion pulmonary edema has yet to be adequately determined but is likely multifactorial. Increased pulmonary vascular permeability appears to be a major factor and is probably related to hypoxic injury to the capillary beds and alveolar membranes. Increased pulmonary capillary pressure and blood flow, decreased surfactant levels, and mechanical damage to the lung also play a role. Rapid removal of air or fluid may result in an abrupt return of circulation and transudation of protein and fluid into the alveolar space. Occasionally an associated shock-like state occurs, with resulting hypotension and evidence of decreased organ perfusion. [81] Treatment includes supportive care, oxygenation, and positive-pressure ventilation when indicated. Patients with hypotension are given volume replacement and inotropic agents as needed. Invasive monitoring is frequently required. The best course is to prevent this complication with slow, staged removal of large effusions or collections of air (especially if they have been present for several days) and avoidance of suction, if possible.

Mechanical problems commonly result in air leaks with failed reexpansion or inadequate drainage. Tension pneumothorax can occur if a blockage in the drainage system at any point is associated with an air leak. Failure of reexpansion or incomplete reexpansion of a pneumothorax may be due to a mechanical air leak, but it may also indicate a bronchopleural fistula, a continued parenchymal lung leak, or a bronchial injury. Retained hemothorax may result from clotting or poor tube function. The largest possible tube should be used for drainage of a hemothorax. Reinsertion or placement of a second tube may be indicated if the first tube is not functioning properly. Often, an angled tube in the posterior diaphragmatic sulcus will promote drainage of a dependent fluid collection. Clotted hemothorax or fibrothorax is an indication for elective decortication and pleurodesis. Subcutaneous emphysema can occur if the chest tube is partially extruded or plugged.

If a chest tube is not functioning properly or has not reversed the pathologic condition as expected, the clinician must carefully reevaluate the position of the chest tube. In an emergency situation, the tube may have been placed subcutaneously, and the incorrect placement may not be obvious to the physician. If the tube dissects in a fascial plane posteriorly along a rib, even the postinsertion film may appear to confirm proper placement. Such a condition may be lethal. As a general rule, *if a chest tube is not functioning properly and the patient is deteriorating, the tube should be removed and inserted again, or another tube should be inserted.*

# Chapter 10 - Carotid Sinus Massage and Cardioversion

**William Burdick**

## Carotid Sinus Massage

The effects of pressure on the carotid sinus have been known for centuries. They were first described in the medical literature in 1799 when Parry wrote a treatise about the "symptoms and causes of syncope anginosa, commonly called angina pectoris," [1] in which he noted that pressure on the bifurcation of the carotid artery produced dizziness and slowing of the heart. The term carotid is derived from the Greek *karos*, meaning heavy sleep.

Carotid sinus massage (CSM) is a technique involving digital pressure on the richly innervated carotid sinus that takes advantage of the externally accessible position of this baroreceptor for diagnostic and therapeutic purposes. Its main diagnostic utility is now in the differential diagnosis of syncope, particularly in the elderly; in the assessment of tachydysrhythmias and rate-related bundle branch block; and as a clue to latent digoxin toxicity. Its main therapeutic application is for termination of supraventricular tachycardias (SVTs) due to paroxysmal atrial tachycardia (PAT).

The use of CSM has been eclipsed in recent years by the use of adenosine, an ultrashort-acting vagal stimulating nucleotide. The diagnostic and therapeutic effects of adenosine on tachydysrhythmias are similar to those elicited by CSM, and its safety is derived from its short duration of action--usually about 10 seconds. Because adenosine may not always be readily available, and because adenosine cannot be used to assess the sensitivity of the carotid sinus, CSM remains a useful tool.

A number of the other therapeutic uses of CSM have also been made nearly obsolete by current medical therapy. CSM was noted in the 1920s to relieve acute pulmonary edema in many patients with hypertensive and coronary artery disease. Lown and Levine describe the dramatic effect: "Relief is immediate and coincides with the onset of bradycardia. In the majority it is associated with a drop in blood pressure. The patient is promptly able to lie flat. Fear, dyspnea, and chest oppression disappear..." [2] CSM also can relieve anginal pain; this technique may be useful when the diagnosis of angina is uncertain. However, the advantage of this technique over the use of nitroglycerin is unknown. Hence, although CSM is no longer the first approach to either of these common clinical problems, it may remain a therapeutic or diagnostic tool in some difficult cases or when modern pharmacologic agents are unavailable.

### ANATOMY AND PHYSIOLOGY

The bifurcation of the common carotid artery possesses an abundant supply of sensory nerve endings located within the adventitia of the vessel wall (Fig. 10-1) (Figure Not Available) . These nerves have a characteristic spiral configuration, continually

intertwining along their course and eventually uniting to form the carotid sinus nerve. The afferent impulses travel to the vasomotor center of the medulla. Efferent impulses travel along the vagus nerve to the sinus node and the atrioventricular (AV) node, as well as along the sympathetic chain to the heart and the peripheral vasculature.

The afferent nerve endings in the carotid sinus are sensitive to mean arterial pressure and to the rate of change of pressure, with pulsatile stimuli found to be more effective than sustained pressure in evoking a response. Elevated blood pressure stretches the baroreceptors, leading to increased firing of the afferent nerve endings. The carotid sinus is even more sensitive to low blood pressure, which causes a drop in afferent firing.

The parasympathetic and the sympathetic nervous systems both play a role in the carotid sinus reflex. Increased firing of the carotid sinus results in reflex stimulation of vagal activity as well as in reflex inhibition of sympathetic output. The parasympathetic effect is almost immediate; it occurs within the first second and causes a drop in heart rate. The sympathetic effect, which causes a drop in blood pressure through vasodilatation, becomes manifest only after several seconds, and it may not take full effect until a minute has elapsed. [3] These are independent phenomena--the fall in heart rate is blocked by the administration of atropine, whereas epinephrine blocks the reduction in blood pressure. A cerebral effect, characterized by a loss of consciousness, was once thought to be due to stimulation of the carotid sinus. However, it is seen only when sufficient pressure is exerted to occlude the more distal temporal artery pulsation and when contralateral carotid disease is present. This cerebral effect is therefore believed to be a result of decreased bilateral cortical perfusion.

The parasympathetic branch of the carotid sinus reflex supplies the sinus node and the AV node. The sinoatrial (SA)

**Figure 10-1** (Figure Not Available) Anatomy of the carotid sinus reflex. Carotid receptors send impulses to the medulla by way of the sinus nerve of Hering and cranial nerve IX. Efferent nerves are shown on the right. *(Adapted from Scher AM: Control of arterial blood pressure. In Ruch TC, Patton HD: Physiology and Biophysics. 20th ed. Vol 2. Philadelphia, WB Saunders, 1974.)*

pacemaker is more likely to be affected than is the AV node, except when digitalis has been administered. In order of decreasing frequency, the changes seen clinically with CSM include (1) SA slowing, occurring in approximately 75% of cases and leading to sinus arrest approximately 3% of the time; (2) atrial conduction defects, manifested by an increase in width of the P wave on the electrocardiogram; (3) prolongation of the PR interval and higher degrees of AV block, seen in approximately 10% of cases; (4) nodal escape rhythms; (5) complete asystole, defined as sinus arrest without ventricular escape lasting greater than 3 seconds, occurring in 4% of cases; and (6) premature ventricular contractions.

## INDICATIONS AND CONTRAINDICATIONS

CSM may be a useful aid to the diagnosis of syncope in the elderly. Some 14 to 45% of elderly patients referred for syncope are thought to have carotid sinus syndrome, [4] [5]

defined as an asystolic pause greater than 3 seconds or a reduction of systolic blood pressure greater than 50 mm Hg in response to CSM. It shares many characteristics with sick sinus syndrome, suggesting that both are manifestations of the same disease. The carotid sinus syndrome causes cerebral hypoperfusion leading to dizziness and syncope. Analysis of patients with the syndrome indicates that it results from baroreflex-mediated bradycardia in 29% of patients, hypotension in 37%, or both in 34%. [6] Syncope, near-syncope, or a fall of unclear etiology in the elderly are therefore important indications for diagnostic CSM.

Another diagnostic indication for CSM is possible digoxin toxicity. Toxicity from digoxin depends more on the response of the host than on the actual digoxin level. In cases of suspected digoxin toxicity when the digoxin level is in the "normal range," or before the level is available, CSM may be a useful diagnostic adjunct. Significant inhibition of AV node conduction associated with ventricular ectopy, and especially ventricular bigeminy, should lead to suspicion of digoxin toxicity. [2]

The clinician can take advantage, however, of the similarity of the vagal effects of digoxin and CSM. Before starting digoxin administration in a patient, the practitioner can gauge the cardioinhibitory effect that will be achieved with the drug by first performing CSM. Significant slowing or block with CSM suggests a similar sensitivity to digoxin, and a smaller loading dose should be considered.

CSM also is indicated in settings in which slowing conduction in the SA or AV node could provide useful information. These settings include patients with wide complex tachycardia in whom CSM aids in the distinction between SVT and ventricular tachycardia (VT), elucidates narrow complex tachycardia in which the P waves are not visible, or aids in detection of suspected rate-related bundle branch block or suspected pacemaker malfunction. After CSM, a wide complex SVT may be converted to normal sinus rhythm, P waves may be revealed after increased AV node inhibition, or ventricular complexes may narrow as the ventricular rate slows. Because CSM slows atrial and not ventricular activity, AV dissociation may be more easily seen, indicating VT (Fig. 10-2) (Figure Not Available) . In rapid atrial fibrillation, or atrial flutter with 2:1 block, either P waves or irregular ventricular activity with absent P waves may be revealed. Sinus tachycardia may also be more apparent once P waves are unmasked by slowing the SA node (Figs. 10-3 (Figure Not Available) to 10-9) (Figure Not Available) . Adenosine may be used for the same diagnostic purpose in these situations as well.

CSM is *contraindicated* in patients likely to suffer neurologic or cardiovascular complications from the procedure. Patients with a carotid bruit should not have CSM because of the risk of carotid embolization or occlusion. A recent cerebral infarction is another contraindication, because even marginal reduction of cerebral blood flow may produce further infarction.

The presence of diffuse, advanced coronary atherosclerosis is associated with increased sensitivity of the carotid sinus reflex. This hypersensitivity is further augmented during an anginal attack or an acute myocardial infarction. Brown and coworkers found that the degree of carotid sinus hypersensitivity was directly

proportional to the severity of coronary artery disease documented by cardiac catheterization. [7] Patients with acute myocardial ischemia or with recent myocardial infarction are already at higher risk of VT or ventricular fibrillation (VF), and a prolonged asystole may further predispose them to these dysrhythmias. CSM should therefore also be avoided in these patients.

Both digoxin and CSM act through a vagal mechanism to inhibit the AV node. Patients on digoxin may experience a greater inhibition of the AV node with longer AV block as a result. Patients with apparent manifestations of digoxin toxicity or known digoxin toxicity should not have CSM, as AV inhibition may be profound.

## EQUIPMENT AND SETUP

Generally, as a precaution against hypotension, an intravenous (IV) line with normal saline should be started before attempting CSM, and the patient should be placed on a cardiac monitor. Atropine and lidocaine, as well as a transvenous or transcutaneous pacemaker and defibrillator, should be readily available at the bedside in case a life-threatening dysrhythmia develops. The clinician should first auscultate for carotid bruits on both sides of the neck before attempting CSM--the presence of a bruit is a contraindication to massage.

The patient should be in the supine or slight reverse Trendelenburg position if it can be tolerated. Occasionally PAT will convert merely by lowering the back of the bed, presumably because the supine position results in a stretching of the carotid bulb, giving maximum baroreceptor sensitivity. The supine position may also prevent syncope in the event of a significant drop in heart rate or blood pressure.

Berk and colleagues have demonstrated in healthy volunteers that cold-water face immersion and the Valsalva maneuver can produce a greater vagal response than CSM. [8] Mehta and colleagues also found that the Valsalva maneuver was more effective than CSM for conversion of induced SVT. [9] The pneumatic antishock garment has also been used to similarly increase vagal tone by stretching the carotid bulb (see Chapter 30) . [10]

## TECHNIQUE

The clinician should begin CSM on the patient's right carotid bulb as some investigators have found a greater cardioinhibitory effect on this side, [8] [9] although no difference was found in one study. [11] Simultaneous bilateral CSM is absolutely contraindicated, because cerebral circulation may be severely compromised.

Keeping the patient relaxed is helpful for two reasons: a tense platysma muscle makes palpation of the carotid sinus difficult, and an anxious patient will be less sensitive to CSM as a result of heightened sympathetic tone.

With the head tilted backward and slightly to the opposite side, palpate the carotid artery just below the angle of the mandible at the upper level of the thyroid cartilage and

anterior to the sternocleidomastoid muscle. Once the pulsation is identified, use the tips of the fingers to administer CSM for 5 seconds in a posteromedial direction, aiming toward the vertebral column. Although earlier practitioners used longer duration of massage, a shorter period of massage minimizes the risk of complications and is adequate for diagnostic purposes in the majority of patients. [12] Pressure on the carotid sinus may be steady or undulating in intensity; the force, however, must not occlude the carotid artery. The temporal artery may be simultaneously palpated to ensure that the carotid remains patent throughout the procedure.

If unsuccessful, CSM may be repeated after 1 minute. If the procedure is still unsuccessful, the opposite carotid sinus may be massaged in a similar fashion. Simultaneous Valsalva maneuver may also enhance carotid sinus sensitivity.

## COMPLICATIONS

Neurologic complications of CSM are rare and are usually transient. In a recent review of neurologic complications in elderly patients undergoing this procedure, Munro and others found 7 complications from a total of 5000 massage episodes, for an incidence of 0.14%. [13] Reported deficits included weakness in 5 cases and visual field loss in 2 others. In 1 case the visual field loss was permanent. Patients in this study were excluded from CSM if they had a carotid bruit, recent cerebral infarction, recent myocardial infarction, or a history of VT or VF. The duration of massage was 5 seconds. Lown and Levine described 1 patient with brief facial weakness during several thousand tests. [2] Carotid emboli and hypotension have both been implicated as possible causes of the neurologic deficits. Unintentional occlusion of the carotid artery may also be responsible for some neurologic complications.

Cardiac complications include asystole, VT, or VF (Fig. 10-10) . A normal pause of <3 seconds is part of the physiologic response to CSM; a longer pause may be diagnostic of carotid sinus syndrome. In a review of reported cases of ventricular tachydysrhythmias, 5 cases were described. [14] All 5 patients were receiving digoxin, and in several cases, VT or VF followed AV block. Digoxin is associated with more prolonged AV block resulting from CSM, perhaps leaving these patients more vulnerable.

## INTERPRETATION

A pause >3 seconds, or a drop in systolic blood pressure >50 mm Hg in patients to whom CSM is administered while they are in a supine position, is diagnostic of the carotid sinus syndrome (Fig. 10-11) (Figure Not Available) . Patients should be supine during testing to reduce the risk of cerebral hypoperfusion.

When approaching patients with a tachydysrhythmia, the following principles can guide the interpretation of results (Table 10-1) :

1. CSM may slow the atrial rate in VT or complete heart block and may therefore demonstrate previously hidden P waves or obvious AV dissociation.

2. Abrupt changes in the heart rate without conversion are a result of increasing AV block.
3. Gradual slowing of the ventricular rate suggests the presence of a sinus rhythm. Only rarely does CSM decrease AV conduction in the presence of a sinus mechanism.
4. The dysrhythmias most likely to convert to sinus rhythm are PAT and paroxysmal nodal tachycardia.
5. Dysrhythmias that are associated with AV conduction defects (PAT with block, atrial flutter, atrial fibrillation) infrequently convert to a sinus rhythm, but the ventricular rate slows. Rarely, atrial slowing will be sufficient to allow 1:1 AV conduction, which may actually increase the ventricular rate (Fig. 10-12) (Figure Not Available) .

## CONCLUSIONS

The advent of adenosine and effective medications to treat congestive heart failure has diminished the therapeutic use of CSM. It still remains an important diagnostic tool, however, to determine the presence of the carotid sinus syndrome in patients with syncope. CSM should not be performed in patients with a carotid bruit, those who have had a recent stroke, or those with digoxin toxicity. Patients with coronary artery disease will have an enhanced response to CSM, and the technique should be used with care in these patients.

# Cardioversion

Cardioversion is the application of direct electrical current across the chest or directly across the ventricle to normalize the conduction pattern of a rapidly beating heart. Defibrillation refers to application of electrical energy to restore a fibrillating ventricle to normal sinus rhythm (see Chapter 11) .

The patient with a significant tachycardia may be asymptomatic or may complain of chest pain or discomfort, light-headedness, or shortness of breath. These symptoms are the result of altered cardiovascular physiology. Rapid cardiac rhythms allow less time for ventricular filling, resulting in reduced preload and hypotension. The reduced preload as well as the increased ventricular work caused by the rapid heart rate may also result in ventricular ischemia. Pulmonary capillary wedge pressures may also rise despite shortened filling time, due to reduced ventricular compliance secondary to ventricular ischemia. Elevated pulmonary capillary wedge pressures can then lead to pulmonary edema.

Termination of rapid rhythms to alleviate or prevent these symptoms must occur quickly to prevent further deterioration. Persistently poor cardiac output due to rapid heart rate results in development of a lactic acidosis that further compromises cardiac function and makes cessation of the dysrhythmia even more difficult. Unchecked myocardial ischemia may lead to infarction with its attendant sequelae. Drug therapy, rapid cardiac pacing, and cardioversion are the methods available to terminate tachydysrhythmias.

In many cases, direct-current cardioversion has specific advantages over drug therapy. The speed and simplicity of electrical cardioversion enhance its usefulness in the emergency department setting. Cardioversion is effective almost immediately, has few side effects, and is often more successful than drug therapy in terminating dysrhythmias. In addition, the effective dose of many antidysrhythmic medications is variable, and there is often a small margin between therapeutic and toxic dosages. Although they can often suppress an undesirable rhythm, drugs may also suppress a normal sinus mechanism or may create toxic manifestations that are more severe than the dysrhythmia being treated.

In the clinical setting of hypotension or acute cardiopulmonary collapse, cardioversion may be life saving. The key

**Figure 10-11** (Figure Not Available) Hyperreactive carotid sinus reflex. Gentle pressure was applied to the carotid sinus for 3 seconds, resulting in a pause in sinus rhythm of approximately 7 seconds. This syndrome may be the cause of syncope. *(From Bigger JT Jr: Mechanisms and diagnosis of arrhythmias. In Braunwald E (ed): Heart Disease. Vol. 1. Philadelphia, WB Saunders, 1980. Reproduced by permission.)*

| Paroxysmal atrial tachycardia (PAT) | 1. No effect or abrupt termination of dysrhythmia. |
| PAT (Wolff-Parkinson-White syndrome) | 1. Varying results (slowing, no effect, termination). 2. CSM may unmask Wolff-Parkinson-White syndrome by increasing anomalous AV conduction. |
| Paroxysmal AV junctional tachycardia | 1. No effect or termination of dysrhythmia. |
| Nonparoxysmal junctional tachycardia | 1. No response. 2. *Caution:* CSM may be dangerous if rhythm results from digitalis toxicity. |
| Ventricular tachycardia | 1. No response in ventricular rate. 2. CSM may uncover AV dissociation by demonstrating P waves or a decrease in atrial rate. 3. If rhythm is ventricular parasystole, response may be variable. |
| Digitalis-toxic rhythms | 1. CSM should not be attempted. |

concepts in the use of this procedure include understanding the indications for its use, the equipment involved, the importance of adequate sedation, and the concerns for health-worker safety.

## BACKGROUND

The first successful defibrillation of the human heart was performed in 1947 by Beck. By the 1960s, electrical energy was being used to treat dysrhythmias other than VF. Alternating current remained in vogue until 1962, when Lown and colleagues advocated direct current countershock as the method of choice for terminating atrial fibrillation. [15] The use of direct current significantly decreased the incidence of VF following countershock (Fig. 10-13) (Figure Not Available) .

A brief burst of electrical current momentarily causes depolarization of the majority of cardiac cells and allows the sinus node to resume normal pacemaker function. In reentrant dysrhythmias, such as paroxysmal SVT and VT, cardioversion restores sinus rhythm by interrupting a self-perpetuating circuit. Cardioversion is much less effective in terminating tachycardias resulting from augmented automaticity, such as digitalis-induced dysrhythmias.

**Figure 10-12** (Figure Not Available) Acceleration of ventricular rate by carotid sinus stimulation (CSS). Continuous tracing. Upper strip shows 2:1 atrioventricular block: atrial rate = 102/min; ventricular rate = 51/min. The second and third strips were recorded during and after CSS, when the atrial rate was reduced to 68/min; a 1:1 response occurs. *(From Lown B, Levine SA: Carotid sinus--clinical value of its stimulation. Circulation 23:766, 1961. Reproduced by permission.)*

## INDICATIONS AND CONTRAINDICATIONS

Cardioversion is indicated whenever there is a reentrant tachycardia causing chest pain, pulmonary edema, lightheadedness, or hypotension. This excludes those tachydysrhythmias that are known to be caused by digitalis toxicity as well as a known sinus tachycardia. It also is indicated in less urgent circumstances when medical therapy has failed. In elderly patients, in whom a prolonged rapid heartbeat can be anticipated to cause complications related to cardiac ischemia or dysfunction, early intervention with cardioversion may also be beneficial.

A reentrant tachydysrhythmia should be suspected when a sudden change in the heart rate occurs within a few beats. Unless the dysrhythmia is noted while the patient is being monitored, it can only be inferred from the patient's history of sudden onset of symptoms. In the unusual case of sinus-node reentrant tachycardia, rapid onset and offset may be the only clue. [16] Other clues to the presence of a reentrant dysrhythmia are a history of Wolff-Parkinson-White syndrome or another known accessory pathway syndrome. Ventricular rates in excess of those predicted for age strongly suggest an accessory pathway.

Dysrhythmias due to enhanced automaticity will not be terminated by uniformly depolarizing myocardial tissue because a homogeneous depolarization state already exists.

Enhanced automaticity is the cause of most cases of digitalis toxicity-induced dysrhythmia, sinus tachycardia, and, probably, multifocal atrial tachycardia. [17] Enhanced automaticity means that the threshold for phase 4 depolarization has been lowered or that the rate of ion leak during phase 4 has been accelerated. This effect on phase 4 depolarization is caused by alterations in the metabolic or chemical environment or on the cell membrane, causing pacemaker cells to fire more rapidly. Although cardioversion will not work in these cases, medications that suppress

automaticity, including potassium and magnesium, may be useful.

In digoxin toxicity, cardioversion is not only ineffective; it is also associated with a higher incidence of postshock VT and VF. [18] However, for a patient with a therapeutic digoxin level, the risk of cardioversion is now thought to be no different from that of other patients. [19] Digoxin is still generally withheld for 24 hours prior to cardioversion as a precaution against inadvertently elevated levels. Pregnancy at any stage is not a contraindication to cardioversion. [20] [21]

## EQUIPMENT AND SETUP

The critical components of preparation for cardioversion are IV access, airway management equipment, drugs for sedation, and monitoring and direct current delivery equipment (cardioverter).

Secure IV access is essential for delivery of sedatives, antidysrhythmics, fluids, and, possibly, paralytic agents. Although many of these drugs are not used routinely, if they are needed, timing is likely to be critical. A saline lock catheter of at least 20 ga should be inserted and firmly taped to the patient's skin.

A significant and preventable complication of procedures involving sedation is hypoventilation leading to hypoxia. Airway management equipment includes the secure IV catheter discussed above, working suction with tonsil-tipped device attached, bag-valve mask apparatus, oxygen, and appropriately sized laryngoscope and endotracheal tube (see Chapters 1 and 2) . A pulse oximeter is generally recommended for patients undergoing conscious sedation (see Chapters 6 and 35) . Another adjunct is continuous $pCO_2$ monitoring (see Chapter 6) . A rising $pCO_2$ level will be an earlier clue to hypoventilation due to sedation, because the $O_2$ saturation may remain normal for several minutes, especially if the patient has been preoxygenated.

Sedative medications (see Chapter 35) should be ready for use in labeled syringes, with a prefilled saline syringe available for flushing the catheter. Antidysrhythmic medications for ventricular dysrhythmias (e.g., lidocaine and bretylium) and for unexpected bradycardia (e.g., atropine) should be readily accessible.

The cardioverter device consists of 5 components (see Fig. 10-13) (Figure Not Available) : (1) a direct current depolarizer, which provides varying amounts of electrical current; (2) an oscilloscope screen for monitoring heart rate and rhythm; (3) access to a continuous electrocardiogram (ECG) readout to document the patient's course and response to treatment; (4) 2 removable electrode paddles, which can be applied easily to the patient's chest wall; and (5) a synchronizer, permitting discharge of energy outside the vulnerable period of the cardiac cycle. The synchronizer permits triggering of the electrical discharge by the R or S wave of the ECG (Fig. 10-14) (Figure Not Available) .

**Figure 10-14** (Figure Not Available) Phases of vulnerability for atrium and ventricle. Note that an alternating current shock of 0.20 second may end at the T wave even when synchronized with the R wave of the electrocardiogram. *(From Resnekov L: Theory and practice of electroversion in cardiac*

Paddles must be large enough to depolarize the majority of heart fibers simultaneously; therefore, most conventional paddles have an electrode diameter of at least 4 inches. Larger paddles also limit the risk of myocardial injury by decreasing the density of current passing through the myocardium.

## TECHNIQUE

If time permits, metabolic abnormalities such as hypokalemia and hypomagnesemia should be corrected before attempting cardioversion. At a minimum, hypoxia should be corrected with supplemental $O_2$ . If a patient has metabolic acidosis, compensatory hyperventilation after endotracheal intubation may be indicated prior to cardioversion. Respiratory acidosis should always be treated prior to the use of sedative drugs.

### Sedation

Cardioversion may be extremely painful or terrifying, and *patients must be adequately sedated prior to its use*. Patients who are not adequately sedated may experience extreme anxieties and fear. [22] Several IV medications are available for sedation of patients prior to cardioversion. These include etomidate (0.15 mg/kg), midazolam (0.15 mg/kg), methohexital (1 mg/kg), propofol (1.5 mg/kg), and thiopental (3 mg/kg). [23] [24] In addition, fentanyl (1.5 mug/kg), a synthetic opioid analgesic, is sometimes administered 3 minutes prior to induction.

Midazolam (Versed) is probably the most commonly used agent, with induction occurring about 2 minutes after a dose of about 0.15 mg/kg, or at least 5 mg for an average-sized adult. Although induction with midazolam takes slightly longer than the other medications, it has the advantage that a commercial antagonist, flumazenil, is available for reversal if necessary. Small additional doses of fentanyl (1 to 1.5 mug/kg) may be added for more profound sedation. Fentanyl can cause respiratory depression, but it is reversed with naloxone. Methohexital has the advantage of quick onset and somewhat shorter duration than midazolam, but it has a rare association with laryngospasm. All the drugs except etomidate cause a small drop in blood pressure, and infusion of propofol and etomidate is painful.

In elderly patients the pharmacodynamics and kinetics are altered by coexisting illness and polypharmacy, rather than by any intrinsic effect of old age. [25] Older patients with medical conditions such as congestive heart failure, renal failure, cancer, or malnutrition will therefore experience deeper, prolonged sedation with increased respiratory depression. Drug dose should be reduced in these patients.

Administer the anesthetic agent(s) IV over about 30 seconds and wait until the patient is unable to follow simple commands and loss of the eyelash reflex is noted. Pushing the agent too quickly may result in hypotension; pushing the agent too slowly may not allow blood levels to reach a therapeutic range, if the agent has a rapid rate of metabolism.

**Cardioverter Use**

Selection of synchronized or nonsynchronized mode is the next critical step. In "synchronized" mode, the cardioverter searches for a large positive or negative deflection, which it interprets as the R or S wave. It then automatically discharges an electric current that lasts <4 msec, avoiding the "vulnerable" period during repolarization when VF can be easily induced. When the cardioverter is set to "synchronize," a brief delay will occur after the buttons are pushed for discharge, as the machine searches for an R wave. This delay may be disconcerting to the unaware operator.

If concern exists about whether the R wave is large enough to trigger the electrical discharge, the clinician can place the lubricated paddles together and press the discharge button. Firing should occur after a brief delay. When the R- or S-wave deflection is too small to trigger firing, change the lead that the monitor is reading or move the arm leads closer to the chest. If there is no R or S wave to sense, as in VF, then the cardioverter will not fire. *Always turn off "synchronization" if VF is noted.*

**Electrode Contact**

A number of substances can be used to ensure good contact between the paddle and the skin (see Chapter 11) ; it is necessary that they be nonflammable and have a low electrical resistance. Conductive gel or paste is most commonly used, but waxy conductive pads are also available. Generous use of conductive gel on the underside and especially along the edges of the electrode paddles is essential, both to reduce transthoracic impedance and to prevent skin burns. Paste should be applied liberally but must not run onto the skin between the paddles, because the paste may divert current over the skin surface and away from the heart. Even under ideal circumstances only 10 to 30% of the total current passes through the heart, so diversion over the skin may significantly reduce the effectiveness of an electric discharge. Saline-soaked pads are therefore generally not desirable. Pre-gelled adhesive electrode pads are useful if available.

**Electrode Position**

Electrode paddles may be positioned in 2 ways on the chest wall: (1) the anterolateral (or base and apex) position, with one paddle placed in the left fourth to fifth intercostal space, midaxillary line, and the other just to the right of the sternal margin in the second to third intercostal space (Fig. 10-15) (Figure Not Available) ; or (2) the anteroposterior position, with one paddle placed anteriorly over the sternum and the other on the back between the scapulae (Fig. 10-16) (Figure Not Available) . The anterolateral position is used for emergent cardioversion, when placement of an electrode on the patient's back may not be feasible. Paddles should be pressed firmly against the skin to avoid arcing or skin burns.

Safety is a key concern in the performance of cardioversion. Any staff member acting as a ground for the electrical discharge can be seriously injured. The operator must

announce "all clear" and give staff a chance to move away from the bed before discharging the paddles. Care must be taken to clean up spills of saline or water, because they may create a conductive path to a staff person at the bedside.

**Energy Requirements**

The amount of energy required for cardioversion varies with the type of dysrhythmia, the degree of metabolic derangement, and the configuration and thickness of the chest wall (Table 10-2) . Obese patients may require a higher energy level for cardioversion; the anteroposterior paddle position is sometimes more effective in these patients. If patients are shocked while in the expiratory phase of their respiratory cycle, energy requirements may also be lower.

Ventricular tachycardia in a hemodynamically stable patient should be treated with lidocaine followed by procainamide, and bretylium should be given if necessary. If these drugs are unsuccessful, cardioversion is then used. Cardioversion

*Figure 10-15* (Figure Not Available) Anterolateral paddle electrode position. *(From Suratt PM, Gibson RS: Manual of Medical Procedures. St Louis, CV Mosby, 1982. Reproduced by permission.)*

with 10 to 20 J is successful in converting VT in more than 80% of cases. Cardioversion will be accomplished with 50 J in 90% of cases, and conversion should be initially attempted at this energy level. [26] Cardioversion should be synchronized unless the T wave is large and could be misread as the R wave by the cardioverter. If this is unsuccessful, the energy level should be doubled, and doubled again if necessary, until a perfusing rhythm is restored. Immediately following conversion of VT, antidysrhythmic medication should be given to prevent recurrence.

Patients with pulseless VT should be initially shocked with 200 J, followed by 300 J if the first shock is not successful.

Reentrant SVTs generally respond to low energy levels. Atrial flutter, for example, usually requires <50 J for conversion. [27] Cardioversion of atrial flutter in the emergency department is indicated when the ventricular rate is not slowing in response to pharmacologically enhanced AV-node blockade, or if the patient is unable to tolerate the aberrant rhythm.

The majority of patients with PAT respond to adenosine. If they do not, or if urgent conversion is needed due to high ventricular rate, electric countershock should be administered in the synchronized mode at 50 J, and doubled if necessary.

In atrial fibrillation, the response to cardioversion is dependent on the duration of atrial fibrillation and the underlying cause. Cardioversion is successful in 90% of cases

* Note: "Synchronization" always used.
For elective cardioversion of atrial fibrillation, 3 weeks of prior warfarin therapy is suggested. Embolic rates are highest following cardioversion in patients with mitral stenosis, enlarged left atrium, and history of embolic disorders. Quinidine is usually given before or after cardioversion to maintain sinus rhythm. Attempts to cardiovert patients with digitalis toxicity can lead to VT/VF. This is not seen with therapeutic digoxin levels.

secondary to hyperthyroidism but in only 25% of cases secondary to severe mitral regurgitation. [28] However, 50% of cases revert within 6 months, especially those with long-standing atrial fibrillation. [29] [30]

Most patients with atrial fibrillation do not require cardioversion in the emergency department unless their ventricular response is high due to a bypass tract, as in Wolff-Parkinson-White syndrome. They may also require cardioversion when sequelae of rapid ventricular contraction are present or anticipated and the ventricular rate is not responding to drug therapy aimed at slowing AV node conduction. Conversion of atrial fibrillation generally requires more energy than the reentrant SVTs (about 100 J in most cases). [31]

**COMPLICATIONS**

Complications of cardioversion may affect the patient, particularly the patient with a cardiac pacemaker, as well as health care personnel at the bedside. Patient complications are dose related and may involve the airway, heart, or chest wall, or they may be psychological.

Injuries to health care personnel with cardioversion/defibrillation include mild shock and burns, and there is a reported incidence of 1 injury per 1700 shocks for paramedics in the field. [32] Of the 13 injuries reported in this study, 15% were due to equipment failures, 23% were due to injuries during testing or demonstrations, and 23% were due to arcing of the electric shock from the paddle to an electrode on the patient's chest, whereas the remainder were due to direct contact with the patient or with the stretcher.

Hypoxia may result if sedation is excessive or if the airway becomes compromised. With proper preparations and precautions, airway complications can be minimized.

Respirations may also be depressed by any of the anesthetic agents,

and adequacy of tidal volume must be continually assessed by either direct observation or end-tidal $CO_2$ monitoring. If another physician is available, he or she should be placed in charge of monitoring the patient's airway. Routine supplemental $O_2$ is suggested for all patients undergoing sedation.

Chest wall burns resulting from electrical arcing are generally superficial partial-thickness burns, although deep partial-thickness burns have occurred. [33] These are preventable by adequate application of conductive gel and firm pressure on the paddles. Paddles should not be placed over medication patches or ointments, especially those containing nitroglycerin, because electrical discharge may cause ignition resulting in chest burns. [34]

Cardiac complications following cardioversion are proportionate to the energy dose delivered. In the moderate energy levels used most commonly, the hemodynamic effects are small. At higher energy levels, however, complications include dysrhythmias, hypotension, and, rarely, pulmonary edema, which may occur several hours after the countershock. [35] A transient failure of myocardial $O_2$ extraction due to a direct effect on cellular mitochondria has been proposed as an explanation for some of these cardiac complications. [36]

The dysrhythmias following high-dose (approximately 200 J) direct-current shocks include VT and VF, bradycardia, and AV block, in addition to transient and sustained asystole. Sustained VT or VF was reported following 7 of 99 shocks in a study of patients undergoing electrophysiologic study and requiring cardioversion for VT, VF, or atrial fibrillation. [37] These episodes occurred only in the patients with prior VT or VF. Patients with ischemia or known coronary artery disease appear to be at much higher risk for significant postshock bradycardia, with rate support pacing required after 13 of 99 shocks in the study. Asystole requiring pacing occurred only once in 99 countershocks.

Two types of VF following cardioversion have been described. The first variety occurs immediately after countershock and is easily reversed by a second, nonsynchronized shock. This type of VF results from improper synchronization, with discharge of current occurring during the vulnerable period. The second variety, which is more ominous, occurs approximately 30 seconds to a few minutes following attempted cardioversion. This dysrhythmia is characteristically preceded by the development of PAT with block or a junctional rhythm. In affected patients, it may be very difficult to convert the dysrhythmia to a sinus rhythm. This phenomenon occurs in patients who have been taking digitalis glycosides and is presumably a manifestation of digitalis toxicity (Fig. 10-17) (Figure Not Available) . [38] [39]

In the event of VF following cardioversion, the equipment and manpower are present for immediate defibrillation. If postcardioversion VF occurs, switch the cardioverter to "nonsynchronized" before attempting defibrillation. Electrical discharge will not occur in the "synchronized" mode, because the machine will be searching for a nonexistent R

wave.

VF is much more likely to occur if depolarization occurs on the T wave. If a patient has large T waves in the lead selected for cardioverter sensing, the electric shock may discharge during the vulnerable period of the cardiac cycle, resulting in VF. [40] Always examine the complexes on the cardioverter monitor carefully for large T waves and, if necessary, change the sensing lead. A randomly firing pacemaker can also be sensed by the cardioverter, resulting in countershock during the vulnerable period. [41]

Transient and intermittent ST-segment elevation has also been reported to occur (though rarely) after cardioversion, with myocardial injury or coronary vasospasm offered as possible explanations. [42]

An increase in serum enzyme levels (creatine kinase, lactate dehydrogenase, aspartate aminotransferase) may also occur following cardioversion, and the incidence has been reported to be between 10 and 70%. The enzyme rise is usually a consequence of skeletal muscle injury rather than myocardial damage. Cardioversion does not alter the enzyme profile of patients with myocardial infarction. [43]

## CONCLUSIONS

Cardioversion is a safe and effective method of quickly terminating reentrant tachycardia. Complications related to psychological trauma, respiratory depression, and unintentional health-worker shock can be avoided with proper precautions. Adequate sedation is essential. Synchronized shock should be administered after close scrutiny of the lead used for sensing, to be sure that the R or S wave is significantly larger than the T wave. Be prepared for postshock VT or VF, and if VF occurs, switch the cardioverter to "nonsynchronized" and defibrillate. Atropine and temporary pacing equipment should be available to treat postshock bradycardia, especially in patients with myocardial ischemia or infarction.

# Chapter 11 - Defibrillation

**Jerris R. Hedges, Michael I. Greenberg**

Ventricular fibrillation (VF) can be associated with myocardial ischemia or infarction, marked electrolyte disturbances, electrical injuries, pronounced hypothermia, or drug toxicity (e.g., that caused by cyclic antidepressants, quinidine, and digitalis). Because this rhythm is clearly incompatible with life, it must be treated rapidly and effectively. Electrical defibrillation is defined as the conversion of VF to an alternative (preferably supraventricular) rhythm. Although brief periods of VF with spontaneous reversion to a sinus rhythm have been recorded, VF is usually irreversible without such electrical countershock. [1]

Ventricular fibrillation is the primary cause of most cases of sudden cardiac death. [2] Contrary to popular belief, the majority of victims of sudden death have not suffered a myocardial infarction. Rather, VF is the culprit. However, many victims of sudden death have evidence of advanced coronary disease, although it may have been previously asymptomatic. In addition, survivors of sudden death attributable to VF are at increased risk of suffering a recurrence, although this chance may be lessened with the use of long-term beta-blocker therapy. [3] [4]

With the advent of portable defibrillation units and out-of-hospital and in-hospital cardiac resuscitation teams, the challenge of providing early defibrillation treatment to the potential victim of sudden death in VF is being addressed aggressively. It has been estimated that 10-35% of out-of-hospital VF cardiac arrest victims could be saved if closed chest cardiac massage and artificial ventilation were provided in <4 minutes and followed by defibrillation in <8 minutes of collapse. [5] [6] However, optimal survival rates depend on prompt recognition and treatment of VF; several recent urban studies report an overall survival to discharge rate of only 2-4% in patients experiencing out-of-hospital VF cardiac arrest. [7] Although survival from VF is highly dependent on many variables, the timeliness of defibrillation may be the most important intervention determining the prognosis in out-of-hospital cardiac arrest. [8] Because prompt, effective defibrillation is equally important for in-hospital VF cardiac arrests, all physicians and nurses should ideally be thoroughly familiar with this procedure.

## BACKGROUND

The concept of electrical shock therapy in resuscitation can be traced to the experiments of Abildgaard in the 18th century. Abildgaard described chickens as being "lifeless" following electrical shocks and noted successful resuscitation after the use of additional shocks. Subsequent animal studies were reported by Preust and Batelli. [9] In 1947 the first successful human defibrillation using the direct application of electrical current to the heart was reported by Beck and coworkers. [10] Nine years later, Zoll and colleagues reported the first successful cardiac defibrillation in a clinical setting using an alternating current (AC) electrical shock applied externally to the thorax. [11]

Portable direct current (DC) defibrillators were introduced by Lown and colleagues [12]

and Edmark and coworkers [13] during the 1960s. DC defibrillators opened the way for out-of-hospital defibrillation modalities. Although the basic design of modern defibrillators has not changed much since the 1960s, modifications in paddle size, energy delivered, energy waveform, conducting materials, and pharmacologic enhancement of defibrillation have been topics of active investigation since the mid-1970s.

## INDICATIONS AND CONTRAINDICATIONS

Electrical defibrillation of the heart in the presence of VF is indicated whenever immediate spontaneous conversion to an effectively perfusing rhythm does not occur. "Quick-look" paddles permit immediate monitoring of the arrested patient's rhythm before electrical defibrillation. These can be quite helpful in the emergent situation to determine if defibrillation is indicated. Patients who are unresponsive and who have regular tachydysrhythmias as diagnosed by the "quick-look" method are best treated with synchronized cardioversion (see Chapter 10) , although it is important to remember that if monitoring is not immediately available, an initial unsynchronized countershock may be life saving.

The precise timing for defibrillation during resuscitation has been the subject of debate, but most authorities are in agreement that an initial electrical shock should be applied to the victim of sudden death before drug administration. In most resuscitations, closed chest cardiac massage and concomitant ventilation support are initiated while the defibrillator is being readied. If the patient is unconscious, apneic, and pulseless, it is reasonable to assume that an episode of VF is occurring if cardiac monitoring is not available with the device. In such instances, an immediate attempt at defibrillation is warranted. Although asystole and, more rarely, ventricular tachycardia (VT) may appear clinically similar, an immediate countershock is unlikely to worsen either clinical situation.

Because "fine" VF can occasionally masquerade as ventricular standstill or asystole, monitoring paddle electrodes should be rotated 90° from their original position or the monitor lead changed before the decision to withhold defibrillation in the victim of sudden death is made (Fig. 11-1) . [14] Low-voltage VF likewise is not a contraindication to defibrillation, because it may reflect low monitor gain or a problem with monitor lead or paddle placement.

## CHARACTERISTICS OF VENTRICULAR FIBRILLATION

VF is characterized on the electrocardiogram (ECG) by the presence of rather low-amplitude baseline undulations that are variable in both amplitude and periodicity. Although many consider VF to represent an electrically random process, electrical directionality to depolarization (i.e., wavefronts) can exist. [14] Mechanically, VF represents an uncoordinated and distinctly disorderly and mechanically ineffective contractile process. Resulting from the lack of effective contractile cardiac function, tissue perfusion is markedly compromised, and if it is not promptly corrected, death

becomes inevitable.

At the tissue level, VF represents a disorganization of the orderly depolarization sequence that usually occurs in the ventricles. Normally, the refractory period of depolarized muscle prevents the development of reentrant ventricular rhythms. When ischemia, electrolyte disorders, cardiac drug toxicities, rapid ventricular rates, hypothermia, and certain other disorders exist, refractory periods may shorten or conduction velocities may tend to increase in certain areas of the ventricle. Wandering depolarization wavefronts that become self-perpetuating can develop. A combination of disorders of impulse formation (automaticity) and impulse conduction (reentry) contribute to the development of VF. [15] [16] The tendency for VF to occur is enhanced by, but is not entirely dependent on, premature ventricular impulses that occur during the "vulnerable" period of the cardiac cycle represented by early ventricular repolarization (T wave). [17]

Asynchronous ventricular depolarization may be confined to a small area of the ventricle if the remaining ventricle is refractory to further stimulation. Several studies have shown that a critical muscle mass is required for VF to be self-sustaining, possibly explaining why VF is so uncommon in infants undergoing resuscitation (who usually die from respiratory arrest). A large mass of muscle involved in asynchronous depolarization having a brief refractory period and a slow conduction velocity increases the tendency for the ventricles to fibrillate.

Cummins and coworkers [18] [19] have classified VF on the basis of average peak-to-trough wave amplitude (Table 11-1) (Table Not Available) . They note that the amplitude of the VF waveform is associated positively with the probability of resuming a perfusing rhythm. However, the clinical importance of coarse vs. fine VF in relation to ultimate survival is unclear. Signals that have an amplitude of <1 mm (when the monitor is calibrated at 10 mm/mV) should be considered to indicate asystole, [18] [19] because countershock of such low-amplitude rhythms is only rarely associated with conversion to a perfusing rhythm. [20] [21]

Electrical defibrillation represents the simultaneous depolarization of sufficient ventricular tissue to render the tissue that is ahead of the VF wavefronts refractory to further electrical conduction. Following generalized depolarization, the sinus node or other pacemaker region of the heart

| TABLE 11-1 -- Classification of Ventricular Fibrillation (VF) Based on Mean Waveform (Peak to Trough Averaged Over a 3- to 6-Second Interval) Amplitude |
| --- |
| (Not Available) |

with the highest degree of automaticity can then acquire dominance of a well-ordered

depolarization-repolarization sequence.

## DEFIBRILLATOR CHARACTERISTICS

General standards and product evaluations for cardiac defibrillation devices are beyond the scope of this chapter. Rather, this section discusses the major components and design configurations of a prototypical defibrillator and how they relate to effective defibrillation.

### Waveforms

Despite the fact that the first successful human defibrillation was performed using alternating current (AC), [10] Lown and others demonstrated that direct current (DC) is more effective than AC in accomplishing defibrillation and results in a significantly reduced incidence of postcardioversion dysrhythmias. [12] Only DC defibrillators are in clinical use today. Most of the modern defibrillators use a damped half-sinusoidal waveform or a trapezoidal (truncated exponential decay) waveform. The trapezoidal waveform can be modified to resemble a square waveform. The more square the waveform, the more effective it is for experimental defibrillation. [22] Furthermore, in a comparison of square waveforms and damped half-sinusoidal waveforms for animal defibrillation, it was found that less peak current per kilogram was needed with the square waveforms, although the average current levels were equivalent. [23] Furthermore, the delivered waveform is dependent on thoracic resistance. In clinical practice, however, there is little clinical difference in the effectiveness of the currently available waveforms.

### Stored Energy

Because the ability to defibrillate is dependent primarily on current delivered to the myocardium, [24] the stored energy is one factor that, coupled with transthoracic impedance and internal defibrillator energy loss, contributes to successful defibrillation. Each defibrillator is calibrated by measuring the current delivered as a function of time across a 50-ohm impedance. It is important to note that defibrillators do not always deliver the energy indicated on the device. With a "stored" energy of 400 J (1 J = 1 watt-sec), from 155 to 410 J may be delivered. It stands to reason that the current (for a square waveform) delivered to the myocardium is related to the energy delivered by the defibrillator, the electrical impedance in the device and chest, and the duration of current flow:

Energy (J) = current (amperes)$^2$ × impedance (ohms) × duration (seconds)

Obviously, any increase in transthoracic impedance will further reduce delivered current.

### Device Switches

Many portable (capable of battery operation) defibrillators have separate power switches for the accompanying monitor and recorder and for the defibrillator. The same

device can be used for cardioversion as well as defibrillation. Before attempting defibrillation, the physician must be completely familiar with the location and operation of the controls. This knowledge will assure that, for example, the operator will avoid attempting to defibrillate a patient when the defibrillator portion is not yet turned on.

Defibrillators also have a control permitting *synchronous cardioversion*. The physician or other operator must be certain that the control is correctly set to the *asynchronous* mode to permit defibrillation; otherwise, the device in the synchronous mode would "wait" indefinitely for a nonexistent repetitive series of R waves prior to discharging.

Energy settings may be determined by a switch or a dial setting or may be read off of a meter permitting a continuous range of settings. In each case the operator must be aware of the need to charge the device initially and to recharge after each discharge. The mechanism of charging the device may be intrinsic to the setting of the dial or meter but more commonly requires the use of a separate charge button on the device control panel or paddle handle. Full charge accumulation usually takes from 2 to 5 seconds following activation of the charging mechanism.

Discharge controls are generally present on the paddle handles, allowing the operator to position and hold the paddles in place while delivering the charge. Alternatively, there may be a separate control on the panel. The simultaneous activation of the control on both paddles is usually required for energy discharge.

Monitor controls permit alteration of lead-monitored image size and often allow the selection of chest lead electrode vs. paddle electrode monitoring. The latter is desirable when an initial "quick-look" rhythm evaluation is desired before placement of the chest lead electrodes. A hard copy paper recorder for documenting rhythms may operate in a real-time, delay, or standby mode.

**Paddles or Electrode Pads**

Most commercial defibrillator devices come equipped with adult-sized paddle electrodes with diameters between 8 and 9 cm. Canine studies have shown that slightly larger (12.8 cm diameter) paddles are more effective for defibrillation, [25] and produce less myocardial injury. [26] Paddles that are slightly smaller (4.5 cm diameter) produce greater damage at the same energies. The larger paddles may permit a greater amount of muscle to be depolarized while simultaneously decreasing the potentially damaging current density. If the paddles are too large with respect to the heart (e.g., if adult paddles are used during infant resuscitation), the current density may be less and defibrillation may be rendered less effective. [27] The recommended minimum diameter for infant transthoracic paddles is 2.2 cm. Atkins and colleagues suggest that because of their reduction in transthoracic impedance, the larger adult electrodes should be used whenever a child's thorax is large enough to permit electrode-to-chest contact over the entire paddle surface. [28] This transition in paddle size occurs at 1 year of age or at an approximate weight of 10 kg. Because the time delay required to change from adult to pediatric paddles may be excessive, the routine use of adult-size paddles on any child who weighs >10 kg is recommended. [29]

Some defibrillators have a flat posterior ground shield rather than a second paddle for lateral chest wall placement.

With the two-paddle system, charge and discharge controls are generally present on the paddles.

The metal composition of the paddle electrode will affect transthoracic impedance to the defibrillation discharge. Most modern defibrillators use stainless steel because of its durability, although copper alloys and several other metals provide a lower transthoracic impedance.

Defibrillation can also be performed with self-adhesive electrode pads applied to the skin. The self-adhesive monitor/defibrillator pads appear to perform as well as or better than hand-held paddles. [30] Stults and colleagues, in a controlled out-of-hospital study, found that the use of self-adhesive pads shortened the time to successful defibrillation, reduced the number of countershocks, reduced the amount of rhythm artifact, and improved survival until hospital admission when compared with the use of standard hand-held paddles. [27] However, the expense of self-adhesive defibrillator pads has limited their general acceptance. If future studies support their superiority in other clinical settings, it is likely that the pads will gain wider acceptance.

**Conductive Materials**

Transthoracic impedance varies with the type of conductive material applied between the paddles and the chest wall. [31] For paddles that are 8.0 cm in diameter, the transthoracic impedance is $91 \pm 20$ ohms for bare contact, $71 \pm 11$ ohms for saline-soaked gauze, and $64 \pm 15$ ohms for Redux Paste. Clearly, electrode-skin agents will reduce impedance and allow more current to be delivered to the heart, but the ideal agent is the subject of some debate. Ewy and Taren recommend that Corgel, Redux Paste, American Writer, GE Gel, Electrode Jelly, or Trucon Electrode Paste be used to minimize impedance. [31] Saline-soaked gauze pads may be used, although one must be careful not to allow the saline, coupling gels, or paste to flow into a "bridge" on the skin between the electrodes, creating a potential fire hazard. Although some form of coupling medium (e.g., paste, cream, gel, pad) should be used to reduce impedance, data conflict regarding which product is optimal. Although Redux Paste (Hewlett-Packard) has been associated with significantly lower transthoracic impedance, a statistically significant increase in the success of defibrillation attempts has not been demonstrated with any specific product.

Hummel and coworkers investigated conductive materials with regard to their potential to overheat and to spark. [32] They found that the products that offer lower impedance (e.g., Redux Paste, Signagel) remained stable and did not spark after 4 or 5 defibrillation discharges, which was seen with the higher impedance products (e.g., Redux Cream, Aquasonic 100, EKG Sol, Spectra 360, and Derma-Jel). [32]

# PROCEDURE

Sudden death victims suspected to be in VF should be defibrillated as quickly as possible (Fig. 11-2) . Current recommendations are that defibrillation be attempted up to 3 times prior to initiating cardiopulmonary resuscitation (CPR), [33] unless additional personnel are on the scene and can perform CPR while the defibrillator device is being readied for use.

After applying conductive material to the entirety of the

**Figure 11-2** Algorithm for management of unwitnessed ventricular fibrillation (VF) or witnessed VF not responsive to precordial thump. After each therapy, the rhythm is reassessed, and the rescuer must evaluate the need for continued treatment for VF. If VF persists, the rescuer continues through the protocol. CPR, cardiopulmonary resuscitation; IV, intravenously.

paddle's conductive surface, the paddles should be firmly applied to the chest wall and held there by the operator. Ideally, the current should pass through the heart. One paddle should be positioned to the right of the upper sternum below the clavicle; the second paddle is placed just to the left of the nipple in the midaxillary line and is centered in the fifth intercostal space (see Fig. 10-15) (Figure Not Available) . Placement of both paddles close together on the anterior chest wall should be avoided. In some paddle sets, each paddle is labeled as either "sternum" or "apex" so that any rhythm detected on the monitor can be properly aligned. This feature is irrelevant

for defibrillation but is important for cardioversion. Anteroposterior paddle positioning is also acceptable and may deliver more current to the heart. The anterior paddle is placed to the left of the sternum over the precordium and the posterior electrode is placed just to the left of the spine directly posterior to the heart (see Fig. 10-16) (Figure Not Available) .

With the monitor turned on and set to display the "paddle" electrodes, the rhythm is evaluated. If a flatline rhythm is detected, the monitor gain must be increased fully in order to rule out the presence of a "fine VF" tracing. Should the tracing remain flat during a brief pause in closed-chest cardiac massage, the paddles should be rotated 90° from the original position and the rhythm reassessed. The incidence of VF masquerading as asystole was approximately 2.5% in 1 out-of-hospital study of patients with an initial flatline monitor rhythm. [19] Other conditions can cause a flatline rhythm during VF arrest. Cummins [33] recommends that the rescuer also check all monitor cable connections to the patient and defibrillator, check the ECG size control, and check the power supply. If VF is observed during any of these maneuvers, defibrillation should proceed without delay. Should a bradycardiac or asystolic rhythm be detected, standard resuscitation measures, including basic CPR, correction of hypoxia, administration of catecholamines, correction of volume or cardiac filling deficiencies, and emergency cardiac pacing, should be initiated when indicated. Although defibrillation should have no theoretical benefit for asystole, the use of countershock will result in the development of a QRS rhythm in a very small percentage of patients with flatline rhythms who receive

such shocks. Presumably, such cases represent instances of fine VF simulating a flatline rhythm on the EGG.

In cases of "fine VF" in which a patient is wearing an implanted (subcutaneous) pacemaker, the pacer spikes may initially appear to be a paced but nonconducted rhythm; attention to the baseline and lack of ST changes characteristic of capture should reveal the true nature of the dysrhythmia. [34] Because injury to the pacemaker pulse generator [35] and to the myocardium can occur by transmission of current down the pacing electrode, the physician must be careful to situate the defibrillator paddle at least 12 cm away from the pulse generator.

In the presence of VF, the paddles should be immediately charged to a stored energy of 2 J/kg for children and 200 J for adults. Keep in mind that separate power switches may be needed to turn on the defibrillator and to store the charge. The amount of charge is usually set by a button or a dial on the control panel. In most devices, the preset level of charge (energy) can be stored if a button on the "apex" paddle is depressed. The physician should always check to be certain that the defibrillator is not in the synchronous (cardioversion) mode.

Once the paddles are charged, the physician should instruct all personnel to "*STAND BACK*" from the patient and the stretcher to avoid stray discharge. However, there is no need for the individual who is bag-tube ventilating the patient to drop the bag and stand back *if their only contact is a rubber or plastic bag*. That individual is not touching conductive materials and will thus be protected from electrical shock. The defibrillator operator, in particular, must be sure that his or her only direct contact with the patient or stretcher is with dry paddle handles. The patient is allowed to exhale passively to minimize transthoracic impedance, [36] while firm (25 lb) pressure is applied through the paddles to the thorax. [37] To minimize energy decay inside the device, the energy in the paddles is discharged through the chest as soon as possible after charging. Simultaneous depression of both paddle discharge buttons is essential for discharge. Anticipation of patient extremity motion subsequent to discharge of the paddles will minimize operator and patient injury.

Should no skeletal muscle contraction occur following simultaneous depression of the discharge buttons, the physician should ensure that firm chest wall contact has been made (some devices will not discharge without adequate contact), that the device is set in the asynchronous mode, that a charge has been stored and that the defibrillator (not just the monitor) is turned on, and the battery is not depleted (when operating off the storage battery). If there is no muscle contraction even when these factors have been ruled out, a replacement defibrillator should be immediately brought into use.

After the first shock, the paddles should remain in place for 5 to 10 seconds to enable the physician to check for an organized rhythm while ventilation is continued. While waiting to analyze the rhythm, the rescuer should recharge the paddles for an immediate second defibrillation (200 to 300 J for adults, 2 to 3 J/kg for children) should VF persist. Should VF continue after the second shock, an immediate third defibrillation (360 to 400 J for adults; 4 J/kg for children) should be given. If the third defibrillation is unsuccessful, closed-chest cardiac massage should be continued, hypoxia corrected,

and alpha-agonist catecholamines administered to elevate the diastolic pressure and to improve coronary perfusion. [38] [39] Following circulation of the catecholamine agent, an attempt at defibrillation should be repeated. Currently there are no convincing data to suggest that "high-dose" epinephrine use is associated with superior long-term survival compared to standard doses in either children or adults. [40]

Infants who develop VF often have underlying cardiac disease and are often taking digitalis preparations. Because excessive defibrillation energy may produce irreversible VF in the patient suffering toxic effects of digitalis, the lowest available energy level should be used for the initial defibrillation. If the initial energy dose is unsuccessful, the energy level can be increased cautiously for successive countershocks.

Additional therapy (see below) can be undertaken to enhance defibrillation. Adequate ventilation, cardiac massage, and correction of electrolyte disorders are intrinsic to every resuscitation and are not discussed further. In addition, evaluation of the patient for hypothermia and rapid core rewarming when indicated (see Chapter 71) should not be overlooked. When practical, electronic monitoring devices and transvenous pacemakers should be turned off or, preferably, disconnected from the patient to avoid equipment damage. Recently manufactured patient monitoring devices, however, have built-in protective filter circuitry, which makes equipment damage an unlikely occurrence.

## ENHANCING DEFIBRILLATION SUCCESS

### Early Defibrillation

Energy requirements for conversion of VF may increase dramatically shortly after the onset of VF. [37] The rationale for

early defibrillation is that in the absence of adequate coronary perfusion, cellular metabolism continues with the depletion of energy substrates and the accumulation of toxic metabolites. Electrophysiologic changes secondary to cellular ischemia develop rapidly and contribute to continued asynchronous transmission of VF wavefronts.

Clinical investigation of immediate defibrillation rather than drug therapy preceding defibrillation is limited. Martin and coworkers, in a retrospective analysis of out-of-hospital VF resuscitation, found that survival until hospital discharge was increased when CPR followed by immediate defibrillation was used rather than CPR and drug therapy before countershock. [41] The group that received drug therapy first had a longer mean time until defibrillation (12 minutes additional), which was explained in part by the time required for IV line placement, drug administration, and drug circulation. Nonetheless, until further clinical studies are available, immediate defibrillation for VF appears to be the most appropriate course of action.

## Transthoracic Impedance

Delivery of current to the heart is dependent on the energy supplied to the paddles and the impedance to transmission of that energy. The greater the impedance or resistance, the less the delivered current. Reported values for human transthoracic impedance using electrodes 8.0 cm in diameter range from 50 to 100 ohms with a mean of 75 ohms. [42] We have previously discussed the importance of paddle electrode composition and size, conductive materials, applied paddle-to-chest-wall pressure, state of ventilation, and location of the paddle on the chest wall (Table 11-2) (Table Not Available) .

The transthoracic impedance of direct current discharge also decreases with higher energy shocks, with increasing number of previous countershocks delivered, [42] [43] and with decreasing interval between the discharges. Unfortunately, each of the aforementioned maneuvers is also associated with an increased potential for myocardial injury.

Nonetheless, one may be faced with the need to defibrillate a very obese patient who is unresponsive to standard paddle placement and maximum device energies. Should such a situation exist, the patient can be rolled on the side and anteroposterior defibrillation attempted. Should this prove unsuccessful, a second defibrillating device can be

| **TABLE 11-2** -- Determinants of Transthoracic Impedance |
| --- |
| (Not Available) |

simultaneously charged and used to administer countershock immediately following discharge of the first defibrillator. It is interesting to note that a canine study of internal defibrillation indicated that 2 sequential shocks over different pathways reduced both total energy and peak voltage required to terminate VF. [44] Hence, sequential defibrillation using slightly different paddle placements may be beneficial independent of the concurrent reduction in transthoracic impedance.

## Energy Choice

Many investigators have referred to a so-called defibrillation energy threshold for converting VF. Davy and coworkers suggest that no unique defibrillation energy threshold exists for the in vivo heart. [45] Experimentally they found that successful defibrillation was related to delivered energy, which follows a typical "dose-response

curve." However, there is evidence for a defibrillation current threshold. [24]

Successful defibrillation is dependent on the simultaneous depolarization of a sizable mass of the myocardium resulting from the passage of current through the heart. For a given thorax, defibrillation device, and defibrillation technique, more current is passed through the heart and, hence, more tissue is depolarized with larger energies. Once sufficient tissue has been depolarized, however, additional current is not desirable and may, in fact, produce additional tissue injury. Kerber and coworkers have suggested that the use of defibrillators that adjust defibrillation energy for the patient's transthoracic impedance (measured by the device just before charging) may be one means to deliver an adequate current to the myocardium while minimizing potential harm. [46] Such devices are not in routine use at present, but they may be helpful in the future for both the identification of high-impedance situations and adjustment of delivered energy. [47]

Several studies have supported the concept that when current needs cannot be predicted nor current delivery measured, a weight-adjusted dosage of energy is preferred for converting VF. Indeed, a dose based on the patient's weight has been found clinically useful for treating children suffering VF. [48] Other prospective human adult studies have questioned the importance of dose strength to conversion of VF. [49] [50] Weaver and coworkers alternated treatment protocols to determine prospectively the merits of 175 J (200 J of stored energy) vs. 320 J (400 J of stored energy) countershocks for defibrillation. [51] On test days, VF patients were shocked initially with one or two 175 J discharges, and all subsequent shocks needed were 320 J. On alternate days, only 320 J shocks were given. The investigators found that 73% (n = 76) of the patients were defibrillated following the first 2 shocks in the low-energy group, whereas 81% (n = 77) of the patients were initially defibrillated in the high-energy group (difference not statistically significant). Asystole occurred in 19% of patients receiving high energy and in 12% receiving low energy. Transient or persistent heart block occurred in 25% of patients shocked with high energy vs. 11% of patients shocked with low energy. Survival until hospital discharge was inversely related to the number of shocks required; no patients who required >8 shocks survived.

Weaver and associates concluded that low-energy (175 J delivered) countershocks were safe, effective, and less cardiotoxic. Obviously, many factors besides discharged energy

play a role in successful defibrillation. Kerber and colleagues have found that defibrillation success rate is a unimodal function of transthoracic current. [52] The maximum defibrillation rate for their patients with a brief duration of VF (<1 minute) occurred at a peak transthoracic current of 38 to 41 amperes (A). Whether a similar optimum transthoracic current is found in patients with prolonged VF remains to be determined. Until energy levels based on measured transthoracic impedance are shown to be predictive of defibrillation success in a variety of settings, most authorities recommend using an initial 200 J energy setting in adults and a 2 J/kg energy setting in children. When 2 sequential defibrillations at this setting are unsuccessful, countershock at 360 J (or maximum output, if needed) is recommended.

## Postdefibrillation Rhythms

Following defibrillation a number of cardiac rhythms may occur. Ultimate prognosis is linked to the rhythm that evolves during the first few minutes following defibrillation. In an evaluation of the prognostic significance of postdefibrillation rhythms in 94 patients, Hoffman and Stevenson [53] noted survival rates of 20-33% in patients who developed a supraventricular rhythm and 8% in those who developed an organized idioventricular rhythm; there were no survivors if defibrillation was unsuccessful or resulted in asystole or an unorganized rhythm. Survival rates may be influenced by the underlying condition or cause of the arrest or by subsequent drug therapy, but ultimate prognosis is dismal indeed if the first few attempts at defibrillation fail to restore a supraventricular rhythm.

## Drug Therapy

The role of correcting hypoxia and electrolyte disorders in the treatment of VF has been discussed previously. The benefit of alpha-agonist catecholamines to enhance aortic diastolic pressure and to improve coronary perfusion has also been described. Further discussion of the role of sodium bicarbonate, adrenergic agents, and antidysrhythmic agents follows. It should be noted that although adjunctive drug therapy is often used or advocated, there are few data supporting better long-term survival rates when any drug therapy regimen is combined with defibrillation. When evaluating any intervention, *it is paramount to focus on survival to discharge and not to be overly concerned with minor changes in initial resuscitation rates that merely provide ultimately unsalvageable patients with transient cardiac activity.* [54]

### Sodium Bicarbonate

The administration of sodium bicarbonate during CPR is controversial, and previous recommendations are currently undergoing reappraisal. [55] Although acidosis can reduce the responsiveness of the myocardium and vascular system to catecholamines, no clinical studies have supported the use of sodium bicarbonate for treatment of VF. Yakaitis and colleagues found that although acidosis did not alter defibrillation success in a canine model of brief VF (75 seconds), prearrest acidosis or hypoxia (in the absence of exogenous epinephrine) was rarely associated with resumption of perfusion. [56] Guerci and coworkers used a prolonged VF (20 minutes of CPR) canine model with epinephrine administration before defibrillation to assess the potential benefit of sodium bicarbonate administration. [57] These investigators failed to demonstrate an advantage from the use of sodium bicarbonate in either defibrillation success or maintenance of perfusion after defibrillation. The influence of acidosis on catecholamines appears to be most prominent at low doses and may not apply to the large amounts of epinephrine used during CPR. Although sodium bicarbonate therapy should be considered for the patient with suspected or proven extreme acidosis, hyperkalemia, or both, it cannot be recommended for routine use as a standard part of the therapy for VF.

There are a number of theoretical reasons to avoid sodium bicarbonate therapy during cardiac arrest. Aside from the fact that it does not specifically facilitate defibrillation and may not be associated with a better final outcome, bicarbonate therapy will shift the

oxyhemoglobin dissociation curve to inhibit oxygen release, induce hyperosmolar and hypernatremic states, produce paradoxical intracellular acidosis through an acceleration of $CO_2$ production, and exacerbate central venous acidosis.

**Adrenergic Agents**

Drugs that stimulate alpha-adrenergic receptors have been advocated during cardiac arrest to increase myocardial and central nervous system blood flow during CPR. These agents may not enhance the ability to defibrillate VF, but they may enhance the development of a perfusing rhythm following defibrillation. [58] It is important to note that alpha agonists are potent vasopressors and that they increase systemic vascular resistance and elevate aortic diastolic pressure, resulting in increased coronary and carotid blood flow. This enhanced perfusion, and not direct beta-adrenergic stimulation, is credited with increased survival rates. [59] In fact, the beta-adrenergic properties of epinephrine and isoproterenol have been postulated to be harmful because these pharmacologic effects increase myocardial oxygen consumption and reduce subendocardial perfusion. When used alone, isoproterenol, a potent beta agonist without alpha effects, does not favorably influence resuscitation rates. Epinephrine has been the vasopressor of choice during CPR, administered in advanced cardiac life support (ACLS) recommended doses of 0.5 to 1.0 mg every 5 minutes. Large doses of epinephrine (0.2 mg/kg), 10 to 15 times higher than currently recommended, may provide better initial resuscitation rates but have not been shown to enhance ultimate survival rates. [40] [60]

A number of pure alpha agonists have been advocated to overcome the theoretical disadvantages of epinephrine. For example, Silvast noted similar resuscitation rates from out-of-hospital cardiac arrest (e.g., from VF, asystole, and pulseless electrical activity [PEA]) when phenylephrine (one or two 1.0-mg boluses) was used in place of standard doses of epinephrine. Methoxamine (10 to 20 mg) has also been used with success rates similar to those of epinephrine. [61] There is concern, however, that although pure alpha agonists favorably augment peripheral vascular resistance, they do so at the expense of cerebral perfusion and myocardial blood flow. [62] [63] The specific role of these agents on defibrillation is unclear. Like high-dose epinephrine, the use of pure alpha agonists in facilitating defibrillation or enhancing long-term survival is not supported by current data. Although adherence to standard ACLS guidelines is logical until the benefits of alternative therapies are clarified, the role of adrenergic adjunctive drug therapy remains controversial.

**Bretylium Tosylate**

Bretylium tosylate has been used to facilitate ventricular defibrillation. Bretylium (Bretylol) has been shown in one animal model to decrease the threshold shock strength required for defibrillation. [64] Other investigators have found no significant effect on the defibrillation threshold. The drug increases the effective refractory period in normal ventricular muscle and Purkinje fibers [65] and enhances electrical uniformity throughout the myocardium, thus tending to terminate conditions supportive of reentrant rhythms. Bretylium raised the threshold for electrically induced VF in a canine CPR model within 10 minutes after administration. [66] Bretylium appears to elevate the VF

threshold by adrenergic neuronal blockade. One canine study has shown an increased potential for PEA with bretylium following defibrillation. [67]

Spontaneous chemical defibrillation has been reported in myocardial infarction patients who were given bretylium by IV drip rather than by bolus perfusion during cardiopulmonary resuscitation. [68] A retrospective study has suggested that the early use of bretylium tosylate during VF sudden death may enhance survival. [69]

For VF, 5 mg/kg of bretylium is given by rapid intravenous bolus, and cardiac massage is performed for 1 to 2 minutes to permit circulation of the drug before defibrillation attempts. If after 2 minutes the initial therapy is unsuccessful, a repeat dose of 10 mg/kg is given, and defibrillatory efforts are continued. Successful defibrillation may be followed by hypotension and the physician must be prepared to administer volume or pressor agents to support the blood pressure.

**Lidocaine**

Lidocaine has long been used to facilitate defibrillation. The rationale for use of lidocaine in VF is primarily based on anecdotal experience. Two studies of nonischemic canines have demonstrated that lidocaine increases the energy required for electrical defibrillation. [62] [70] Kerber and coworkers suggest that the elevation of the defibrillation threshold noted by others may be a function of the anesthetic used in the animal model and may not be a clinical factor. [71]

Lidocaine has complex effects on membrane responsiveness. Little change in conduction velocity occurs in normal myocardium, whereas conduction in ischemic tissue is decreased following lidocaine administration. Lidocaine increases uniformity of the action-potential duration and refractory period throughout the ventricles and can terminate ventricular reentrant rhythms. Lidocaine also raises the threshold for electrically induced VF in a canine CPR model within 5 minutes after administration, although the antifibrillatory effect is not sustained with a single bolus dose.

One retrospective study of out-of-hospital VF arrests documented a small but statistically insignificant improvement in both defibrillation rate and survival when patients refractory to conventional therapy for VF were given lidocaine during the course of their resuscitation. Unfortunately, strict drug and therapy protocols were not followed, and variations in treatment may have masked a beneficial effect of lidocaine administration. Comparison studies of out-of-hospital lidocaine and bretylium use for refractory VF showed similar conversion and survival rates in the 2 drug treatment groups. [72] [73] Although the role of lidocaine and bretylium in the facilitation of defibrillation remains to be defined more clearly, clinical experience suggests that both drugs have value in aiding defibrillation. Because one drug may be more beneficial than the other in a given patient, broader generalizations cannot be made. Certainly both drugs are useful for preventing degeneration of a supraventricular rhythm once effective defibrillation occurs, and one or the other has been empirically advocated to be used postdefibrillation. Lidocaine is initially given as a bolus of 1 mg/kg to the VF sudden death victim who is refractory to conventional defibrillatory efforts. A second 1 mg/kg bolus can be given in 10 to 15 minutes. It is important to remember to reduce the

maintenance (not the initial loading dose) dose of lidocaine in patients who have a history of hepatic and/or left ventricular dysfunction.

**Other Drug Therapies**

As the search continues for useful pharmacologic adjuncts to facilitate defibrillation or to serve as alternatives to countershock, anecdotal reports of success with newer antiarrhythmics have appeared in the literature. No medications are of proven value, but amiodarone and magnesium sulfate have been evaluated in limited clinical trails. Amiodarone is a class III antiarrhythmic that has recently become available in an IV form to treat life-threatening ventricular arrhythmias and VF. Kowey and coworkers suggest that it may be as effective as bretylium [74] in treating recurrent VT and VF, and others have suggested a possible role for this agent in cardiac arrest. [75] [76] Hypotension and bradycardia are common side effects, and the role of amiodarone in facilitating defibrillation remains unclear.

Miller and colleagues have proposed a possible benefit for one to two 5-g bolus injections of IV magnesium sulfate in refractory cardiac arrest. [77] Magnesium has been touted as an antiarrhythmic for years, but its role in cardiac arrest or for enhancing the success of defibrillation is still unclear.

# COMPLICATIONS

The major complications of direct current defibrillation are (1) injury to skin and other soft tissue, (2) myocardial injury, and (3) cardiac dysrhythmias.

## Soft Tissue Injury

When skin contact is firm and a conductive material is applied between the paddles and the chest wall, contact burns are usually minimal. Nevertheless, repeated countershocks can produce erythema of the skin resembling superficial first-degree burns. The presence of liquids (e.g., blood, IV solutions, vomitus, urine, excessive sweat) may permit the passage of current across the trunk. This electrical arcing will produce thermal burns (third-degree at times) and ineffective defibrillation. Hummel and coworkers have shown that repeated defibrillations using certain high-impedance conducting gels are associated with sparking and represent a fire hazard in an oxygen-enriched environment and an explosion hazard in the presence of nitroglycerin ointment or patches. [32] Intrathoracic injuries (extrinsic to the heart) are likely to occur but are difficult to document during the post-resuscitative period and to separate from cardiac injury (e.g., pulmonary edema). [78]

## Myocardial Injury

The direct application of electrical countershock to the heart has long been known to produce epicardial and myocardial injury. Studies have demonstrated that closed-chest defibrillation is capable of producing cardiac injury. Electrical current rather than direct thermal injury produces injury. [79] [80] Multiple countershocks have been shown to

produce ST segment elevation in animals and gradual cell necrosis (over days) with subsequent fibrosis. [81] The lesions are primarily subepicardial at the points of current entrance and exit. Animals receiving less than twice the defibrillation threshold value do not develop significant necrosis. The degree of cardiac injury correlates with increasing energy exposure.

Jones and coworkers, using an in vitro model, have created transient sarcolemmal microlesions during high-intensity electric field stimulation identical to that of defibrillation. [82] These lesions result in a "short-circuit" depolarization of the cells by loss of the normal sodium-potassium gradient across the sarcolemma. When the lesions are limited, the cell can recover after about 60 seconds. However, with extensive lesions, shock-induced cytosolic calcium overload can occur and can result in postshock contracture.

The ability to document anatomic injury to the human heart is limited by the natural reparative process, concurrent ischemic processes producing similar microscopic changes, and the fact that several days are needed for the injuries to manifest themselves. Cardiac isoenzyme (CK MB) levels were shown to rise in patients undergoing elective cardioversion only if the cumulative delivered energy was >475 J. [83] Therefore, standard defibrillation should not generally interfere with the enzymatic diagnosis of myocardial infarction when defibrillation attempts are not excessive and given that fractionated isoenzymes are measured.

Animal studies have shown that ST segment elevation and pathologic changes are increased with more rapidly delivered discharges (1 or 3 seconds vs 15 seconds between discharges). [80] Furthermore, the cumulative energy correlates with myocardial injury for a given dosing schedule. [84]

**Cardiac Dysrhythmias**

The rhythm that one obtains following defibrillation may be ventricular, supraventricular, or flatline (asystole). Laboratory studies have suggested a correlation between the severity of postdefibrillation dysrhythmias and the degree of myocardial damage produced. [85] Reducing the peak current delivered to the heart by changing the waveform of the discharge was associated with fewer dysrhythmias. Weaver and colleagues noted that asystole and transient heart block occurred more commonly with a higher discharge energy in out-of-hospital VF patients. [51] Gueze and Koster also found that postdefibrillation dysrhythmias were more common following prolonged VF and higher-energy-level countershocks. [86]

**Injuries to Health Care Providers**

Any electrical device, including an improperly grounded or poorly insulated defibrillator, can cause injury to the device operator or to others in attendance. Other participants in a resuscitation who touch the patient or the stretcher can also serve as a ground for the defibrillator charge and can sustain electrical injury. Gibbs and coworkers estimate that the rate of paramedic injury during patient defibrillation is 1 per 1700 defibrillatory shocks. [87] They found only 1 paramedic who required hospital admission for therapy

and monitoring of countershock ectopy. Improper use of the device for cranial countershock has been reported to produce short-term memory loss. [88] However, it must be borne in mind that such inappropriate use of these devices could easily cause much more serious injury. Fires resulting from defibrillator sparks in the presence of nitroglycerin patches or ointment, flammable gases, or an oxygen-enriched environment can also injure health care personnel as well as the patient.

## SPECIAL TOPICS IN DEFIBRILLATION

Management of patients with an automatic implantable cardioverter defibrillator (AICD) is discussed in Chapter 12 .

### Automatic External Defibrillators

Automatic external defibrillators have been developed with sophisticated digital software to take advantage of algorithms that can reliably recognize VF. [18] [33] These small, portable, battery-operated devices permit nonparamedic out-of-hospital providers to defibrillate cardiac arrest patients without human rhythm interpretation. [89]

Because the devices monitor and defibrillate through the same skin electrodes, the user must simply place the adhesive electrode pads at the standard locations (right upper sternal and left anterior axillary line below the nipple), turn on the device, and heed warnings to avoid contact with the patient or with any surface in contact with the patient. Detailed discussion of the operation of these devices is beyond the scope of this chapter. The reader is referred to the instruction manual for the individual devices.

### Thump Defibrillation

The precordial thump consists of a firm, sharp, quickly delivered blow applied to the midsternum with a closed fist from a height of about 30 to 38 cm above the anterior chest wall of a pulseless patient. It is believed that such a blow is capable of generating approximately 5 J of energy.

Although such a precordial thump may be of value in witnessed VT/VF arrests, Miller and associates noted no VF conversion in 23 out-of-hospital VF patients. [90] Despite the fact that the rhythm was improved in 3 of 27 VT patients after a precordial thump, the rhythm deteriorated in 12 of the 27 and did not change in the other 12 patients. Caldwell and colleagues reported the results of a precordial thump in 68 cases of VT and 248 cases of VF. [91] They reported 26 favorable cardioversions, including in 5 patients in VF. Because successful internal defibrillation can occur with as little as 1 J following cardiopulmonary bypass, a vigorous precordial thump may create sufficient current flow to defibrillate the heart when the duration of arrest has been brief (i.e., witnessed cardiac arrest).

### Refractory Ventricular Fibrillation

The major determinants of successful defibrillation are the early use of countershock,

adequate oxygenation, lack of serious metabolic derangements, and general health of the patient. Hargarten and colleagues note that few out-of-hospital patients who remain in VF after the fifth shock are

subsequently successfully converted to an effectively perfusing rhythm. [92] Kerber and colleagues note that patients who never defibrillated despite multiple shocks had a prolonged duration of CPR preceding the first shock (21 ± 14 minutes) and systemic hypoxia and acidosis. [93] These conditions were noted to occur in their patients whose initial cardiac arrest rhythm was asystole, severe bradycardia, or PEA.

A number of clinical conditions may result in the inability to convert VF initially or in the recurrence of VF following the first successful defibrillation. Patients with severe hypothermia are often refractory to initial defibrillation and generally require rapid core rewarming to be successfully defibrillated. Severe bradycardia will predispose to lethal escape rhythms, and emergency cardiac pacing may be required. Severe electrolyte disturbances, such as hypokalemia, hypomagnesemia, and hypocalcemia may precipitate refractory VF and be amenable only to the appropriate, rapid correction of the deficient electrolyte. Such situations may occur especially in fad dieters or abusers of diuretic medications. Uncorrected acidosis or hypoxia, such as that seen with drowning, may be the cause of persistent VF. In addition, excessive adrenergic stimulation, such as that seen with cocaine or amphetamine overdose, may require the use of a propranolol infusion before successful defibrillation. As a final note, following defibrillation, all patients should be treated with prophylactic lidocaine (or other appropriate antidysrhythmic therapy) to minimize the chance of recurrent VF.

## Conclusion

Electrical defibrillation is the preferred treatment for VF-related sudden death. Treatment should be initiated as early as possible with strict attention to selection of the proper energy dose as well as to minimization of transthoracic impedance. Although repetitive high-energy shocks may be associated with myocardial injury, this factor has not been found to be a clinical problem at currently recommended energy levels.

# Chapter 13 - Emergency Transvenous Cardiac Pacing

**Georges C. Benjamin**

The purpose of cardiac pacing is to restore or ensure effective cardiac depolarization. Several approaches to pacing exist, including transvenous, transcutaneous (see Chapter 14) , transthoracic, epicardial, endocardial, and esophageal. The transvenous method of endocardial pacing is commonly used and is both safe and effective. In skilled hands, the semifloating transvenous catheter is successfully placed under electrocardiographic guidance in 80% of patients. [1] The technique can be performed in <20 minutes in 72% of patients and in <5 minutes in 30% of patients. As with other medical procedures, it should not be performed without a thorough understanding of its indications, contraindications, and complications. [2]

## BACKGROUND

The ability of muscle to be artificially depolarized was recognized as early as the 18th century. Over the succeeding years, several scattered experiments were reported, and in 1951, Callaghan and Bigelow first used the transvenous approach to stimulate the asystolic heart in hypothermic dogs. [3] Zoll demonstrated the first clinical use of cardiac pacing in humans in 1952. [4] He reported the successful use of an external transcutaneous electrical stimulator in 2 patients with ventricular standstill.

Furman and Robinson demonstrated the transvenous endocardial approach in humans in 1958. [5] They treated 2 patients with complete heart block and Stokes-Adams seizures, reconfirming that low-voltage pacing could completely control myocardial depolarization. The catheter remained in the second patient for 96 days without complication. Other early clinical studies have proved that transvenous pacing is a valuable procedure in medicine. [6] [7] [8] Fluoroscopic guidance was used for placement of the pacing catheter in all of these studies.

In 1964 Vogel and colleagues demonstrated the use of a flexible catheter passed without fluoroscopic guidance for intracardiac electrocardiography. [9] One year later, this technique was used by Kimball and Killip to insert endocardial pacemakers at the bedside. [10] They noted technical difficulties, including intermittent capture, difficulty passing the catheter, and catheter knotting, in 20% of their patients. During the same year, Harris and associates confirmed the ease and speed with which this procedure could be accomplished. [11]

Before 1965 all intracardiac pacing was done asynchronously, which meant that the pacing catheter could cause electrical stimulation during any phase of the cardiac cycle. Asynchronous pacing frequently resulted in the pacemaker firing during the vulnerable period of an intrinsic depolarization; this occasionally caused ventricular tachycardia or fibrillation. In 1967 a *demand pacemaker generator* that sensed intrinsic depolarizations and inhibited the pacemaker for a predetermined period of time was used successfully by Zuckerman and associates in 6 patients. [12]

A further improvement in the pacing catheter was made by Rosenberg and colleagues when they introduced the Elecath semifloating pacing wire. [1] The Elecath was stiffer than the Flexon steel wire electrode. Rosenberg and coworkers achieved pacing in 72% of patients, with an average procedure time of 18 minutes. They also noted that 30% of their patients were paced in 5 minutes or less. [1] The technique of heart catheterization using a flow-directed balloon-tipped catheter was introduced by Swan and Ganz in 1970. [13] This concept was used successfully by Schnitzler and coworkers for the placement of a right ventricular pacemaker in 15 of 17 patients. [14]

In 1981 Lang and colleagues compared the bedside use of the flow-directed balloon-tipped catheter with insertion of a semirigid electrode catheter in 111 perfusing patients. [15] These researchers found a significantly shorter insertion time (6 minutes and 45 seconds compared with 13 minutes and 30 seconds), a lower incidence of serious arrhythmias (1.5% compared with 20.4%), and a lower incidence of catheter displacement (13.4% compared with 32%) with the balloon-tipped catheter. They concluded that the balloon-tipped catheter was the method of choice for temporary transvenous pacing (Table 13-1) .

Kruger and associates reviewed retrospectively the experience of general internists with transvenous pacemaker placement under electrocardiogram (ECG) guidance. [16] A 4% risk of complications and a 14% incidence of electrode malfunction were reported, and these percentages were noted to be similar to those reported by university cardiologists. They concluded that pacemaker placement by primary care physicians was safe and effective when done under ECG guidance without fluoroscopy. Temporary transvenous dual chamber pacing currently is readily available and is generally safe and effective. [17]

## INDICATIONS

The purpose of cardiac pacing is to resume effective cardiac depolarization. In most cases the specific indications for cardiac pacing are clear; however, some controversial areas remain. The decision to pace on an emergent basis requires knowledge of the presence or absence of hemodynamic compromise, the etiology of the rhythm disturbance, the status of the atrioventricular (AV) conduction system, and the type of dysrhythmia. In general, the indications can be grouped into those that cause either tachycardias or bradycardias (Table 13-2) . Transcutaneous cardiac pacing has become the mainstay of emergent cardiac pacing and is often used pending placement of the transvenous catheter or to determine whether potentially terminal bradyasystolic rhythms will respond to pacing.

## Bradycardias

### Sinus Node Dysfunction

In a review of 200 initial pacemaker implants at Montefiore Hospital during 1975, 36.5% were used for sinus node dysfunction; 11.3%, for sinus arrest; 20.2%, for tachybrady (sick sinus) syndrome; and 5%, for sinus bradycardia. [18] Patients without myocardial infarction who present with symptomatic sinus node dysfunction should be promptly paced if medical therapy fails. Escher and Furman note that pacing is indicated until the etiology of the dysrhythmia is clarified and stability is ensured. [19]

In the asymptomatic patient, a more intensive cardiac evaluation is required to decide whether pacing will be beneficial. This evaluation frequently includes 24-hour Holter monitoring, noting sinus node recovery times, and coronary care unit monitoring.

Sinus bradycardia occurs in an average of 17% of patients with acute myocardial infarction. [20] Sinus bradycardia occurs more frequently in inferior than in anterior infarction and has a relatively good prognosis when accompanied by a hemodynamically tolerable escape rhythm. However, sinus bradycardia is not a benign rhythm in this situation; it has a mortality rate of 2% with inferior infarction and 9% with anterior infarction. [21] Several mechanisms have been suggested to explain sinus node dysfunction with infarction. Among these, ischemia of the node or its neurologic controls [21] and reflex slowing secondary to pain play dominant roles. [22] Sinus node dysfunction

frequently responds to medical therapy but requires prompt pacing if this fails.

**Asystolic Arrest**

Transvenous pacing in the asystolic or bradyasystolic patient has little value. In 1 study of 13 patients who had suffered cardiac arrest, capture of the myocardium was noted in 4 patients, but there were no survivors. [23] Transvenous pacing alone may also not be effective in postcountershock pulseless

bradyarrhythmias. [24] This failure of pacing has also been demonstrated with transcutaneous pacemakers, suggesting that failure of effective pacing is primarily related to the state of the myocardial tissue. [23] Other causes of failure to pace include catheter malposition and dislodgment of the pacing wire during closed-chest massage. [23] Cardiac pacing may be used as a "last ditch" effort in bradyasystolic or asystolic patients but is rarely successful and is not considered standard practice. Early pacing is essential when done for this purpose, if success is to be achieved. [25] A more complete discussion of pacing in bradyasystolic cardiac arrest appears in Chapter 14 .

**Atrioventricular Block**

Atrioventricular block is the classic indication for pacemaker therapy. In symptomatic patients without myocardial infarction and in the asymptomatic patient with a ventricular rate below 40, pacemaker therapy is indicated. [26]

In patients with acute myocardial infarction, 15 to 19% progress to heart block: approximately 8% develop first-degree block, 5% develop second-degree block, and 6% develop third-degree block. [27] First-degree block progresses to second- or third-degree block 33% of the time, and second-degree block progresses to third-degree block about one third of the time. [28]

Atrioventricular block occurring during anterior infarction is believed to occur because of diffuse ischemia to the septum and conduction tissue infranodally. *These patients tend to progress to high-degree block without warning and are often prophylactically paced temporarily, even without hemodynamic compromise.*

During inferior infarction, early septal ischemia is the exception, and block develops serially from first degree to Mobitz type I second degree, then to third degree. These conduction abnormalities frequently result in hemodynamically tolerable escape rhythms because of sparing of the bundle branches. The hemodynamically unstable patient who is unresponsive to medical therapy should be paced promptly. When the stable patient should be paced is unclear, but placing a transcutaneous pacer is one option that can be tried before placing a transvenous pacing catheter.

One study in which the indications for temporary and permanent pacemaker insertion were reviewed in 432 patients with myocardial infarction concluded that patients with second- or third-degree atrioventricular block should be paced, because a higher incidence of sudden death or recurrent high-degree block over the following year was

found in patients who were not continuously paced. [29]

**Trauma**

In the patient with nonpenetrating chest trauma, several rhythm and conduction disturbances have been documented. In these patients, traumatic injury to the specialized conduction system may predispose the patient to life-threatening dysrhythmias and blocks that can be treated by cardiac pacing. [30]

Hypovolemia and hypotension can cause ischemia of conduction tissue and cardiac dysfunction. [31] Continued marked bradyarrhythmias after vigorous volume replacement may respond to cardiac pacing in patients with such trauma. [32]

## Bundle-Branch Block and Ischemia

Bundle-branch block occurring in acute myocardial infarction is associated with a higher mortality rate and a greater incidence of third-degree heart block than uncomplicated infarction. Atkins and associates noted that 18% of patients had bundle-branch block with myocardial infarction. [33] Of these patients, complete heart block developed in 43% who had right bundle-branch block and left axis deviation, in 17% who had left bundle-branch block, in 19% who had left anterior hemiblock, and in 6% who had no conduction block. The investigators concluded that right bundle-branch block with left axis deviation should be prophylactically paced.

A study by Hindman and colleagues confirmed the natural history of bundle-branch block during myocardial infarction. [34] In their study, the presence or absence of first-degree atrioventricular block, the type of bundle-branch block, and the age of the block (new versus old) were used to determine the relative risk of progression to type II second-degree or third-degree block (Table 13-3) (Table Not Available) .

Because of the increased risk, most physicians would pace the following conduction blocks: *new-onset* left bundle-branch block, right bundle-branch block with left axis deviation or other bifascicular block, and alternating bundle-branch block. [34] One authority recommends prophylactic pacing for all new bundle branch blocks when myocardial infarction is evident. [35]

Whether to place a transvenous pacemaker prophylactically in patients with left bundle-branch block before insertion of a flow-directed pulmonary artery catheter remains controversial. Some researchers strongly advocate this procedure because of the risk of transient right bundle-branch block and life-threatening complete heart block. [36] One study notes that this risk is low in patients with prior left bundle-branch block but continues to recommend temporary catheter placement for all cases of *new* left bundle-branch block. [37] One solution to this problem is to place a transcutaneous pacemaker before catheterization as an emergency measure should heart block develop. In these cases, a temporary transvenous pacemaker can be placed in a semi-elective manner when needed. [38]

**Tachycardias**

Hemodynamically compromising tachycardias are usually treated by medical means or electrical cardioversion (see Chapter 10) . Since 1980, there has been an increasing interest in pacing therapy for symptomatic tachycardias. Supraventricular dysrhythmias, with the exception of atrial fibrillation, respond well to atrial pacing. By "overdrive" pacing the atria at rates 10 to 20 beats/min faster than the underlying rhythm, the atria become entrained, and when the rate is slowed, the rhythm frequently returns to normal sinus. A similar procedure is done for ventricular dysrhythmias. [39] Overdrive pacing is especially useful for recurrent prolonged Q-T interval arrhythmias such as those seen with quinidine toxicity or torsades de pointes. [40] Transvenous pacing also is useful in patients with digitalis-induced dysrhythmias in whom direct current (DC) cardioversion may be dangerous or in patients in whom there is further concern about myocardial depression with drugs.

## CONTRAINDICATIONS

There are no absolute contraindications to transvenous cardiac pacing; however, the severely hypothermic bradycardic patient can often be managed without pacing. Severe hypothermia will occasionally result in ventricular fibrillation when pacing is attempted. Because ventricular fibrillation under these conditions is difficult to defibrillate, caution is advised when considering pacing the severely hypothermic and bradycardic patient. Rapid warming is often recommended first, followed by pacing if the patient's condition does not improve.

## EQUIPMENT

Several items are required to insert a transvenous pacemaker adequately. Like most special procedures, a prearranged tray is convenient. The usual components required to insert a transvenous cardiac pacemaker are listed in Table 13-4 .

**Pacing Generator**

Many different pacing generators are available, but in general, they all have the same basic features. The on/off switch frequently will have a locking feature to prevent the generator from inadvertently being switched off. An amperage knob allows the operator to control the amount of electrical current delivered to the myocardium, usually 0.1 to 20 mA. The pacing control mode is the gain control for the sensing

---

**TABLE 13-4** -- Equipment

| **Pacemaker Tray** |
| --- |
| 10-mL syringe |
| 1% lidocaine |
| Alcohol wipes |
| Povidone-iodine (Betadine) |
| Several gauze pads |
| 4 sterile drapes |
| No. 11 scalpel blade |
| 0.9 normal saline--2 ampules |
| Sterile gloves |
| Needle holder |
| Two 22-ga needles |

| |
|---|
| Scissors (suture) |
| Two 4-0 silk sutures on needles |
| Sterile basin |
| **Electrical Hardware** |
| Insulated connecting wire with alligator clamps at each end (or a male-to-male adapter) |
| Spare 9-V battery |
| Medtronic pacing unit no. 5375 |
| 3 Fr Balectrode Pacing Kit (catalog no. 11--KBE1) |
| 12-lead electrocardiographic machine (well grounded) |

function of the generator. By increasing the sensitivity, one can convert the unit from a fixed rate (asynchronous mode) to a demand (synchronous mode) pacemaker. In the fixed rate mode, the unit fires despite the underlying intrinsic rhythm; the unit does not sense any intrinsic electrical activity. In the full-demand mode, however, the pacemaker senses the underlying ventricular depolarizations, and the unit does not fire as long as the patient's ventricular rate is equal to or faster than the set rate of the pacing generator. A sensing indicator meter and rate control knob are also present. An example of a pacing generator is shown in .

**Pacing Electrodes**

Several sizes and brands of pacing catheters are available. In general, most range from 3 Fr to 5 Fr in size and are approximately 100 cm in length. Along the catheter surface are lines that are marked at approximately 10-cm intervals; these can be used to estimate catheter position during insertion. Two basic types of pacing catheters are currently in use: the flexible semifloating or floating catheter, and the rigid fixed-position catheter. [40]

The flexible catheters are more advantageous than the rigid catheter in their ability to be inserted in low flow states, as well as in their decreased tendency to perforate the ventricle. For emergency pacing, the 4 Fr semifloating bipolar electrode with or without the balloon tip is used most frequently (Fig. 13-2) . The balloon holds approximately 1.5 mL of air, and some of them have a locking lever to secure balloon expansion. Before insertion, the balloon is checked for air leakage by inflating it and immersing it in sterile water. The presence of an air leak is noted by a stream of bubbles arising at the surface of the water. An inflated balloon helps the catheter "float" into the heart in low flow states but is obviously not advantageous in the cardiac arrest situation.

For all practical purposes, temporary transvenous pacing is accomplished with a bipolar pacing catheter. The terms *unipolar* and *bipolar* refer to the number of electrodes in contact with that portion of the heart that is to be stimulated. All pacemaker systems must have both a positive (anode) and a negative (cathode) electrode; hence, *all stimulation is bipolar.* In the typical bipolar catheter used for temporary transvenous pacing, the cathode (stimulating electrode) is at the tip of the pacing catheter. The anode is located 1 to 2 cm proximal to the tip, and the two electrodes may be separated by a balloon or an insulated wire. The electrodes are usually platinum rings that encircle the pacing catheter. When properly positioned, both electrodes will be within the right ventricle so that a field of electrical excitation is set up between the electrodes. With the bipolar catheter, the cathode does not need to be in direct contact with the endocardium for pacing to occur, although it is preferable to have direct contact.

A unipolar system is also effective but is infrequently used for temporary transvenous pacing. In a unipolar system, the cathode is at the tip of the pacing catheter, and the anode is located (1) in the pacing generator itself, (2) more proximal on the catheter (outside the ventricle), or (3) underneath the skin on the patient's chest. The bipolar system may be converted to a unipolar system by simply disconnecting the positive proximal connection of the bipolar catheter from the pacing generator and running a new wire from the positive (pacing generator) terminal to the patient's chest wall. Such a conversion may be required in the unlikely event of failure of one lead of the bipolar system.

Theoretically, the field of electrical stimulation of a pacing catheter is equal to the distance between the electrodes. If the field of excitation is not close enough to the myocardium, depolarization will not occur. When a catheter is passed blindly in an emergency, it seems advantageous to ensure the best chance of capture by separating the electrodes by more than the standard 1 to 2 cm. A pacing catheter that uses this configuration (Davison pacing lead, Electro-Catheter Corporation) is a hybrid of the standard bipolar and unipolar catheters. This catheter has the cathode at the tip, but the

anode is situated 19 cm proximal to the tip. This configuration allows pacing with a very wide field of excitation. Pacing has been reported to occur with this catheter when the catheter is placed anywhere within the thoracic venous system. The catheter is a hybrid because both electrodes are present on the same catheter (bipolar), but both electrodes will not be positioned in the same cardiac chamber (unipolar).

### Electrocardiographic Machine

An ECG can be used to record the heart's inherent electrical activity during pacer insertion and to aid in localization of the catheter tip without fluoroscopy. The ECG machine must be well grounded to prevent leakage of alternating current, which can cause ventricular fibrillation. Such leakage should be suspected if interference of 50 to 60 cycles per second (Hz) is noted on the ECG.

The ECG machine should be placed in such a manner as to allow easy visibility of the rhythm during insertion. One method is to place the machine on the same side of the patient as the operator at the level of the midthorax (Fig. 13-3) . Note that the operator stands at the head of the patient during internal jugular or subclavian vein passage of the catheter and at the midabdomen for femoral or brachiocephalic vein insertion.

### Introducer Sheath

An introducer set or sheath is required for venous access (see Chapter 24) . Some pacing catheters are prepackaged with the appropriate equipment, whereas others require a separate set. The introducer set is used to enhance passage of the pacing catheter through the skin, subcutaneous tissue, and vessel wall. To allow passage of the pacing catheter, the sheath must be one size larger than the pacing catheter. A makeshift sheath can be made with an appropriate-sized intravenous (IV) catheter. For the 3 Fr balloon-tipped catheter, a 14-ga, 1.5- to 2-in. IV catheter is suitable. The 4 Fr balloon-tipped catheter will also fit through a 14-ga catheter or needle.

A balloon-directed pulmonary artery catheter (Paceport pacing system, American Edwards Laboratories, American Hospital Supply Corporation) has been developed that has a separate lumen that allows the passage of a transvenous pacing catheter. [42] This catheter is 7.5 Fr and has an opening 19 cm from the catheter tip that allows passage of the 2.4 Fr pacing wire. This stainless steel wire is Teflon coated for easy passage and has a flexible tip. Combination pulmonary artery or pacemaker catheters are also available but are not widely used in the emergency setting.

Overall, the key to success with this procedure is preparation. It is imperative that one examine all the components of the tray before starting the procedure and ensure that all wires, sheaths, dilators, and syringes fit as expected.

## PROCEDURE

### Patient Preparation

Patient instruction is an extremely important aspect of any procedure. Frequently there is not enough time to give patients a detailed explanation. Nonetheless, sufficient information should be provided so that the patient feels at ease. Patients should be assured that they will feel no discomfort after the venipuncture site has been anesthetized and that they will feel better when the catheter is in place and is functional. Continued reassurance is required during the procedure, because patients are usually facing away from the operator; because their faces are often covered, they may be unsure of what is occurring.

All operators should wear surgical masks, caps, gloves, and gowns to decrease the risk of infection before catheter placement. This aseptic precaution should also be explained to the patient.

**Site Selection**

The four venous channels that provide an easy access to the right ventricle are the brachial, subclavian, femoral, and internal jugular veins (Table 13-5) . The route selected is often one of personal or institutional preference. The right internal jugular and the left subclavian veins have the straightest anatomic pathway to the right ventricle and are generally preferred for temporary transvenous pacing. In some centers a particular site is preferred for permanent transvenous pacemaker placement, and, if possible, this site should be avoided for temporary placement.

The subclavian vein can be accessed by both an infraclavicular and a supraclavicular approach; the infraclavicular approach is most commonly reported for all temporary transvenous pacemaker insertions. This route is preferred because of its easy accessibility, close proximity to the heart, and ease in catheter maintenance and stability. The supraclavicular approach has been described in the literature for several years and has gained popularity among some physicians. [43] The left subclavian vein is preferred because of the less acute angle traversed when compared with the right-sided approach.

Some physicians believe the internal jugular approach is as easy as and safer than subclavian catheterization. [44] The right internal jugular vein is preferred because of the direct line to the superior vena cava. Problems with this approach include dislodgment of the pacemaker with movement of the head, carotid artery puncture, and thrombophlebitis (see Chapter 24) .

During cardiopulmonary resuscitation, the use of the right internal jugular vein and the left subclavian veins for pacemaker insertion have been demonstrated to result in the highest rates of proper placement in the right ventricle. [45] The right internal jugular vein is the more direct route of the two and may be the most appropriate site. Because of the extremely low flow state during cardiopulmonary resuscitation, a larger (5 Fr), semirigid catheter may be a more appropriate choice than the 3 to 4 Fr catheters commonly used.

Femoral veins, like neck veins, are reusable and easily catheterized. Problems include

easy dislodgment, infection, and increased risk of thrombophlebitis. [46] [47]

Brachial vein catheterization is easy to perform but results in a high incidence of infection and vessel thrombosis. [48] In addition, the catheter is easily dislodged with arm motion. This approach is seldom used in the emergency setting.

**Skin Preparation and Venous Access**

The skin over the venipuncture site is cleaned twice with an antiseptic solution such as povidone-iodine and isopropyl alcohol. A wide area is prepared because of the tendency for guide wires and catheters to spring from the hands of the unsuspecting operator. Preparation of the skin is shown in Chapter 24 . Similarly, wide draping is carried out in the standard manner to maintain a sterile field and to allow clear visibility of the venipuncture site.

The infraclavicular approach is used in this chapter to illustrate venous access, although the mechanics are generally the same for other vascular approaches. The reader is referred to Chapter 24 for the specific techniques of venous access.

| | **TABLE 13-5** -- Advantages and Disadvantages of Pacemaker Placement Sites | |
|---|---|---|
| **Venous Channels** | **Advantages** | **Disadvantages** |
| Brachial | Very safe route Vessel easily accessible, either by cutdown or percutaneous approach | Often requires cutdown Easily displaced and poor patient mobility Not reusable if cutdown technique is performed Catheter is more difficult to advance than with central or larger vessels |

| Subclavian | Direct access to right heart (especially via leftsubclavian) Rapid insertion time Reusable Good patient mobility | Pneumothorax and other intrathoracic trauma are possible |
|---|---|---|
| Femoral | Direct access to right heart Rapid insertion time Reusable | Increased incidence of thrombophlebitis Can be dislodged by leg movement and poor patient mobility Infection |
| Internal jugular | Direct access to right heart (especially via right internal jugular) Rapid insertion time Reusable | Possible carotid artery puncture Dislodgment with movement of the head Thrombophlebitis |

Occasionally a patient who already has a central venous line in place requires the emergent placement of a pacing catheter. An existing central venous pressure (CVP) line can be used to place the pacing catheter if the catheter lumen is large enough to accept a guide wire. The CVP line should be withdrawn 1 to 2 in. to expose an area of sterile tubing. The tubing is transected through a sterile area while being held firmly at the skin level. A guide wire can then be passed through the tubing, and the tubing can be withdrawn, leaving only the wire in the vein. The guide wire and the tubing should never be released, because embolization may result. An introducer unit can then be passed over the guide wire, as is done in the Seldinger technique (see Chapter 21) , and the pacing catheter can be placed (Fig. 13-4) .

**Pacemaker Placement**

**Electrocardiographic Guidance**

The patient should be connected to the limb leads of an ECG machine, and the indicator should be turned to record the chest (V) lead.

With newer ECG machines, the pacemaker may be attached to any of the V leads (usually $V_1$ or $V_5$ ) that are displayed during rhythm monitoring. As the tracing on the ECG is slightly delayed with the newer devices, advancement of the catheter after initial

insertion must be carefully evaluated.

The pacing wire should be inserted about 10 to 12 cm into the selected vein. The *distal terminal* of the pacing catheter (the cathode or lead marked negative, "-") must be connected to the V lead of the ECG machine by a male-to-male connector or by an insulated wire with an alligator clip on each end (Fig. 13-5) . The pacing catheter is thus an exploring electrode that creates a unipolar electrode for intracardiac ECG recording. The ECG recorded from the electrode tip *localizes the position of the tip of the pacing electrode*. If a balloon-tipped catheter is used, the balloon is inflated with air *after* the catheter enters the superior vena cava.

The pacing catheter should be advanced both quickly and smoothly. The V lead should be monitored, and the P wave and QRS complex should be observed to ascertain the location of the pacing catheter tip. The use of an ECG to guide the placement of a pacing catheter is based on two concepts. First, the complex will vary in size depending on which chamber is entered. For example, when the tip of the pacing catheter is in the atrium, one will see large P waves, often larger than the corresponding QRS complex. Second, the sum of the electrical forces will be negative if the depolarization is moving away from the catheter tip and positive if the depolarization is moving toward the catheter tip. Therefore, if the catheter tip is *above* the atrium, both the P wave and the QRS complex will be negative (i.e., the electrical forces of a normally beating heart will be moving away from the catheter tip). As the tip progresses inferiorly in the atrium, the P wave will become isoelectric (biphasic) and will eventually become positive as the wave of atrial depolarization advances toward the catheter tip. The ECG resembles an aVR lead initially when in the left subclavian vein (Fig. 13-6 (Figure Not Available) *A*) or midsuperior vena cava (Fig. 13-6 (Figure Not Available) *B*). At the high right atrium, both the P wave and QRS complex are negative; the P wave is larger than the QRS complex and is deeply inverted (Fig. 13-6 (Figure Not Available) *C* and *D*). As the center of the atrium is approached, the P wave becomes large and biphasic (Fig. 13-6 (Figure Not Available) *E*). As the catheter approaches the lower atrium (Fig. 13-6 (Figure Not Available) *F*), the P wave becomes smaller and upright. The QRS complex is fairly normal. When striking the right atrial wall, an injury pattern with a P-Ta segment is seen (Fig. 13-6 (Figure Not Available) *G*). As the electrode passes through the tricuspid valve, the P wave becomes smaller, and the QRS complex becomes larger (Fig. 13-6 (Figure Not Available) *H*). Placement in the inferior vena cava may be recognized by a change in the morphology of the P wave and a decrease in the amplitude of both the P wave and the QRS complex (Fig. 13-6 (Figure Not Available) *I*).

Once the pacing catheter is in the desired position, the balloon is deflated by unlocking it and allowing the air to passively fill the syringe. One should avoid drawing back on the syringe, because this may cause balloon rupture. If the plunger does not move back spontaneously, the operator should assume that the balloon ruptured and should not subsequently place more air into the port. The pacing catheter should be withdrawn and the balloon checked for leaks. If a leak is found, a new pacing catheter should be used.

After successful placement of the catheter within the right ventricle, the tip should be advanced until contact is made with the endocardial wall. When this occurs, the QRS segment will show ST segment elevation (Fig. 13-6 (Figure Not Available) *J*). Ideally,

the tip of the catheter should be lodged in the trabeculae at the apex of the right ventricle; however, pacing may be successful if the catheter is in various other positions within the ventricle or outflow tract.

If the pacer enters the pulmonary artery outflow tract, the P wave again becomes negative, and the QRS amplitude diminishes (Fig. 13-6 (Figure Not Available) *K*). If the catheter is in the pulmonary artery, the pacing catheter should be withdrawn into the right ventricle and readvanced. Sometimes a clockwise or counterclockwise twist of the catheter will redirect its path in a more favorable direction. If catheter-induced ectopy develops, the catheter should be slightly withdrawn until the ectopy stops; then it should be readvanced. Occasionally an antidysrhythmic drug such as lidocaine may need to be given to desensitize the myocardium. Once ventricular endocardial contact is made, the catheter is disconnected from the ECG machine. The proximal positive and negative leads are connected to their respective terminals on the pacing generator. The pacing generator is then set to a rate of 80 beats/min or 10 beats/min faster than the underlying ventricular rhythm, whichever is higher. The full-demand mode is selected, with an output of about 5 mA. The pacing generator is then turned on. If complete capture does not occur or if it is intermittent, the pacer will need to be repositioned. When proper capture occurs, the pacer is tested for optimal positioning. This is done by testing the thresholds for sensing and pacing and with chest radiographs, physical examination, and ECG.

**Catheter Placement Without an Electrocardiograph**

Occasionally it is necessary to use a transvenous pacemaker in an emergency setting when a well-grounded ECG machine is not available. Blind insertion of the transvenous pacing catheter is a safe and effective alternative to placement with ECG guidance. In this technique, the pacing catheter is placed 10 to 12 cm into the venous port and is connected to the pacing generator as noted previously. The pacing rate is selected at *twice* the intrinsic heart rate, and the output is set at an amperage that is too low to capture the ventricle, usually <0.2 mA. The unit is then turned on to first *sense* but *not* to pace. On entering the ventricle, the pacer will sense on every other beat. The balloon can then be deflated, the amperage can be increased to 4 to 5 mA for initiating pacing, and the pacemaker can be advanced to capture the ventricle. If this does not occur within an additional 10 cm, the pacing catheter should be withdrawn to its original position and then advanced again. As with ECG placement, proper positioning must be ensured.

Fluoroscopy is a valuable tool in the placement of transvenous pacemakers. Its use depends on the operator's preference, the patient's condition, and its availability. Generally transvenous pacemakers are not inserted under fluoroscopy without ECG monitoring because of the high incidence of ventricular dysrhythmias. [40]

If the cardiac output is too low to "float" a pacing catheter or if the patient is in extremis, there may not be enough time to advance a pacing catheter using the previously described techniques. Such a situation would be asystole or complete heart block with malignant ventricular escape rhythms (although one can make a case for transthoracic or transcutaneous pacing in such conditions). In such emergent situations, the pacing

catheter is connected to the energy source, the output is turned to the maximum amperage, and the asynchronous mode is selected. The catheter is then blindly advanced in the hope that it will enter the right ventricle and that pacing will be accomplished. The pacing catheter is rotated, advanced, withdrawn, or otherwise manipulated according to the clinical response. The right internal jugular approach is the most practical access route in this situation. In such instances, there is the theoretic advantage of using the previously described Davison catheter, because one is interested in rapid capture only until the patient is stabilized.

**Dual Chamber Pacing**

Synchronous pacing of the atria and ventricle through a *dual-chamber pacing catheter* that senses and paces both atria and ventricles (DDD mode) results in more physiologic pacing with further improvement in cardiac output. It also allows for variations in the atrial rate and improved coordination of atrial and ventricular contractions. This catheter is placed in the same manner as the ventricle-only pacing catheter (VVI mode) but requires greater skill and experience because of the need to properly place the catheter in both the atria and ventricle. When attaching the catheter to the pacing generator, it is important to ensure that the atrial catheter is connected to the atrial electrode and the ventricular catheter is placed to the ventricular electrode. The Medtronic Model 5346 dual-chamber pacemaking generator is available for this purpose. It is capable of pacing in a variety of modes, including DDD mode. [17]

**Testing Threshold**

The threshold is the minimum current necessary to obtain capture. Ideally, this is <1.0 mA, and usually it is between 0.3 and 0.7 mA. If the threshold is in this ideal range, good contact with the endocardium can be presumed.

To determine the threshold, the pacing generator should be placed in the full-demand mode at 5 mA with a rate of approximately 80 beats/min. The amperage (output) should then be reduced slowly until capture is lost. This current is the threshold. This maneuver should be carried out 2 or 3 times to ensure that this value is consistent; the amperage should then be increased to 2½ times the threshold to ensure consistency of capture (usually between 2 and 3 mA).

If one reduces the output to below the threshold and then slowly increases it, there may be a difference in the point at which capture returns. This difference is called *hysteresis* and represents the time interval between sensing and pacemaker firing. If the difference in capture current is >20%, the pacing catheter should be repositioned, because serious dysrhythmias may result if the pacemaker fires during the vulnerable period of repolarization.

The sensing function should be tested in patients who have underlying rhythms. The pacemaker system is again set in full-demand mode with complete capture, and the rate is decreased until it is suppressed by the patient's intrinsic rhythm. This is done several

times to ensure accuracy of the sensing function.

In bipolar systems, another method of evaluating the sensing mode is to take a unipolar ECG from each end of the bipolar lead on a chest lead at one-fourth standardization to permit observation of the entire complex. [40] The voltage of the QRS complex is multiplied by 4 and, if adequate, should be greater than the sensing threshold by >1 mV (Fig. 13-7) (Figure Not Available) . Another method is to set the ECG machine on lead I and to connect the wires from the proximal electrode to the right arm lead and the left arm lead to the distal electrode. A lead I is created, which, when the QRS voltage is multiplied by 4, should also be at least 1 mV more than the sensing threshold.

### Securing and Final Assessment

After the pacemaker's position has been tested for electrical accuracy, the introducer sheath should be withdrawn (Fig. 13-8) and the catheter secured to the skin with suture (e.g., 4-0 nylon or silk). A fastening suture should be sewn to the skin and the catheter tied securely in place. The excess pacing catheter should be coiled and secured in a sterile manner along with the introducer. A large sterile dressing should be applied. Pacemaker function should again be assessed, and a chest film should be taken to ensure proper positioning. Ideal positioning of the pacing catheter is at the apex of the right ventricle (Fig. 13-9) (Figure Not Available) .

A 12-lead ECG should be obtained after transvenous pacemaker placement. If the catheter is within the right ventricle, a left bundle branch pattern with left axis deviation should be evident in paced beats (Fig. 13-10) . If a right bundle-branch block pattern is noted, coronary sinus placement or left ventricular pacing due to septal penetration should be suspected.

With a properly functioning ventricular pacemaker, large cannon waves will be noted on inspection of the venous pulsations at the neck. This is caused by the atria contracting against a closed tricuspid valve. On auscultation of the heart, a slight murmur secondary to tricuspid insufficiency from the catheter interfering with the tricuspid valve apparatus may be evident. [50] A clicking sound heard best during expiration following each pacemaker impulse may also be noted here and is believed to represent either intercostal or diaphragmatic muscular contractions caused by the pacemaker. [51] Note that this can also be a sign of cardiac perforation. [52] On auscultation of the second heart sound, paradoxical splitting may be noted. This represents a delay in closure of the aortic valve because of delayed left ventricular depolarization.

As in any procedure, the patient should then be assessed for improvement in his or her clinical status. An evaluation of vital signs, mentation, improvement in congestive symptoms, and urinary output must be noted. In addition, complications secondary to the procedure should be sought and treated as needed.

## COMPLICATIONS

The complications of emergency transvenous cardiac pacing are numerous and

represent a compendium of those related to central venous catheterization, those related to right heart catheterization, and those unique to the pacing catheter itself (Table 13-6) .

## Problems Related to Central Venous Catheterization

Inadvertent arterial puncture is a well-known complication of the percutaneous approach to the venous system. [53] This problem is usually recognized quickly because of the rapid return of arterial blood. Firm compression over the puncture site will almost always result in hemostasis in 5 minutes or less.

Venous thrombosis and thrombophlebitis are also potential problems with central venous catheterization. Thrombophlebitis, which occurs early after insertion, is said to be a rare complication. Some experts believe that it can be managed without removal of the catheter or anticoagulation. [48] When thrombophlebitis occurs in long-term implanted pacemakers, removal and anticoagulation may be required. In one series, only 0.1% of permanent pacemakers were in this category, and in a small percentage of these, occult malignancies were found. [48] Complete thrombosis of the innominate vein is also a rare problem, with pulmonary embolism an even more uncommon event. [54] Femoral vein thrombosis, however, appears to be a much more common event associated with femoral vein catheterization.  Studies using noninvasive techniques have shown a 37% incidence of femoral vein thrombosis, with 55% of these having ventilation-perfusion scan evidence of pulmonary embolism. [55] Thrombosis in the right atrium may also occur and has been treated successfully with thrombolytic agents. [56]

Pneumothorax is consistently a problem with the various approaches to the veins at the base of the neck. The decision to place a chest tube in patients with this complication depends on the extent of the air leak and the clinical status of the patient (see Chapter 9) . In addition, laceration of the subclavian vein with hemothorax, [57] thoracic duct laceration with chylothorax, air embolism, wound infections, pneumomediastinum, hydromediastinum [58] and hemomediastinum, phrenic nerve injury, [59] fracture of the guide wire with embolization, [60] [61] and catheter or guide wire knotting [62] [63] are all potential complications.

## Complications of Right Heart Catheterization

A common complication of the pacing catheter is dysrhythmia, with premature ventricular contractions being a common occurrence in my experience. One study noted a 1.5% incidence of serious dysrhythmias with a balloon-tipped catheter using ECG guidance, compared with a 32% incidence with the semirigid catheter using fluoroscopic guidance, suggesting that the balloon catheter was the preferred type of catheter. [15] Another study noted a 6% incidence of ventricular tachycardia during insertion. [46] The ischemic heart is more prone to dysrhythmias than the nonischemic heart. [64] The therapy for catheter-induced ectopy involves withdrawing the catheter from the ventricle. This usually stops the ectopy; however, if after repeated attempts it is found that the catheter cannot be passed without ectopy, myocardial suppressant therapy may be used to desensitize the myocardium.

Misplacement of the pacing catheter has been well studied. Passage of the catheter into the pulmonary artery can be diagnosed cardiographically by observing the return of an inverted P wave and the decrease in the voltage of the QRS complex. Misplacement in the coronary sinus may occur and

**Figure 13-10**Electrocardiogram pattern of right ventricular pacemaker.

| | | | | | TABLE 13-6 -- Complications of Transvenous Cardiac Pacing |
|---|---|---|---|---|---|

| Year | Author | No. of Patients | Catheter | Route | Result |
|---|---|---|---|---|---|
| 1969 | Rosenberg et al [1] | 111 | Flexon steelwire vs unipolar semifloating (ECG) | 96 Subclavian 5 Basilic 1 External jugular | 12 inconsistent pacing, 3 local infection, 2 pneumothorax, 1 subclavian artery puncture; 16% complication rate |
| 1973 | Schnitzler et al [14] | 17 | 3 Fr bipolar semifloating balloon (ECG) | Antecubital vein | 2 PVCs, stable pacing, no thrombophlebitis |
| 1973 | Weinstein et al [47] | 100 | 6 Fr bipolar (fluoroscopy) | Femoral | 2 ventricular tachycardia, 2 perforations, 2 required repositionings, 1 questionable thrombophlebitis and pulmonary embolism, 1 local infection |

|---|---|---|---|---|
| 1973 | Lumia & Rios [87] | 142 insertions in 113 patients | Bipolar (fluoroscopy) | 61 Brachial 81 Femoral | 12 ventricular tachycardia and fibrillation in 9 patients, 3 perforations in 2 patients; local hematoma, abscess, and bleeding in 30%; 16.9% complication rate |
| 1980 | Pandian et al [88] | 20 | 5 Fr bipolar (fluoroscopy) | Femoral | 25% deep venous thrombosis |
| 1980 | Nolewajka et al [55] | 29 | 6 Fr cordis (fluoroscopy) | Femoral | 34% venous thrombosis by venogram with 60% of these with pulmonary embolism by VQ scan |
| 1981 | Lang et al [15] | 111 | Balloon, semifloating vs. semirigid | Subclavian | Serious dysrhythmia: 1.5% balloon-tipped, 20.4% semirigid Catheter displacement: 13.6% ± 4.4 days balloon-tipped; 32% ± 1.9 day semirigid |
| 1982 | Austin et al [46] | 113 insertions in 100 patients | 4-7 Fr bipolar (fluoroscopy) | Brachial Femoral | Failure to sense or pace in 37%; repositioning in 37% of brachial insertions; repositioning in 9% of femoral insertions; fever, sepsis, local infection only in femoral insertions; 20% complication rate |

ECG, electrocardiogram; PVC, premature ventricular contraction; VQ, ventilation-perfusion.

should be suspected in the patient in whom a paced right bundle branch pattern on the ECG is seen with right ventricular pacing (Fig. 13-11) . Rarely, a right bundle branch

pattern can be seen with a normal right ventricular position; therefore, all right bundle branch patterns do not represent coronary sinus pacing. [65] Further evidence for coronary sinus location can be obtained by viewing the lateral chest film. Normally, the catheter tip should point anteriorly toward the apex of the heart; however, with coronary sinus placement, the catheter tip is displaced posteriorly and several centimeters away from the sternum (Fig. 13-12) (Figure Not Available) . Other potential forms of misplacement include left ventricular pacing through an atrial septal defect or a ventricular septal defect, septal puncture, extraluminal insertion, and arterial insertions.

Perforation of the ventricle is a well-described complication that can result in loss of capture, [67] hemopericardium, and tamponade. [68] [69] Reported symptoms and signs of this problem include chest pain, pericardial friction rub, and diaphragmatic or chest wall muscular pacing. [70] At least 1 case of a postpericardiotomy-like syndrome and 2 cases of endocardial friction rub have been reported without perforation.

Pericardial perforation is suggested radiographically when the pacing catheter is outside or abuts the cardiac silhouette and is not in proper position within the right ventricular cavity (Fig. 13-13) (Figure Not Available) . [73] ECG clues include a change in the QRS and T wave axis or a failure to properly sense. In suspected cases, a two-dimensional echocardiogram usually demonstrates the catheter's extracardiac position. Uncomplicated perforation can usually be treated by simply pulling back the catheter and repositioning it in the right ventricle.

During the insertion of a temporary pacing catheter when a nonfunctioning permanent catheter is in place, there is a small risk of entanglement or knotting. This potential also exists with other central lines and Swan-Ganz catheters. Frequently these lines can be untangled under fluoroscopy using specialized catheters.

Local and systemic infections, [48] balloon rupture, pulmonary infarction, [74] phrenic nerve pacing, [75] and rupture of the chordae tendineae are also potential complications. [74]

**Complications of the Pacing Electrode**

The complications related to the pacing electrode can be separated into three groups: mechanical, organic, and electrical.

Mechanical failures include displacement, fracture of the catheter, and loose leads. Displacement can result in intermittent or complete loss of capture or improper sensing, malignant dysrhythmias, diaphragmatic pacing, or perforation. Displacement should be suspected with changes in amplitude, with vector changes >90°, or with a change in threshold. [76] Frequently catheter fractures may be detected by a careful review of the chest film or may be suspected because of a change in the sensing threshold. As with displacement, intermittent or complete loss of capture may result.

Organic causes of pacemaker failure result in changes in the threshold or sensing function. [77] Progressive inflammation, fibrosis, and thrombosis may result in more than a doubling of the original threshold. [78] This may occur in 3 to 4 weeks and should be

expected in prolonged temporary pacemakers. Physiologic and pharmacologic factors that affect the threshold have been studied. Sleeping, eating a heavy meal, lowered aldosterone concentration, potassium infusions, [79] and myxedema [80] all increase the threshold by raising the resting membrane potential. The threshold for cardiac pacing tends to decrease with exercise, sympathetic amines, glucocorticoids, and toxic levels of procainamide. [81]

In some patients the atrial contribution to ventricular filling is extremely important. Transvenous ventricular pacing results in loss of the atrial kick and ultimately a decrease in left ventricular stroke volume. This phenomenon is called *postpacer syndrome* and occasionally is severe enough to preclude the use of a pacemaker. [82] A bichamber sequential pacemaker that stimulates the atria and ventricles in sequential fashion is a viable alternative for patients unable to tolerate the loss of the atrial kick. [83]

Electrical problems with pacing include pacemaker generator failure, dysrhythmias, and outside interference. Electrical interference is of occasional importance during aeromedical transport. [84] Usually converting the unit to a fixed mode will permit continued pacing. Although ventricular tachycardia and ventricular fibrillation have been reported to result from pacemakers, these dysrhythmias are rare. Because of this, patients who present with such dysrhythmias should be evaluated for a nonpacemaker etiology. [85] Direct current cardioversion and electroshock therapy are safe procedures to carry out in patients who have pacemakers as long as the current does not go directly over the generator pack.

## CONCLUSION

Temporary transvenous pacing is a rapid, safe, and reliable method for achieving effective electrical stimulation of the heart. It can be mastered by any physician who is responsible for the care of critically ill or injured patients. Symptomatic bradycardias unresponsive to pharmacologic treatment and some tachycardias are indications for its use. In acute myocardial infarction, it serves both a therapeutic and a prophylactic function.

# Chapter 12 - Assessment of Implanted Pacemaker/AICD Devices

**David W. Munter**

Patients with permanent implanted pacemakers or automatic implantable cardioverter-defibrillators (AICDs) are commonly seen in the emergency department (ED). At least 500,000 patients in the United States have permanent pacemakers, [1] with as many as 300,000 pacemakers placed or replaced annually. [2] More than 10,000 AICDs have been implanted in patients. [3]

Recipients of these devices have underlying cardiac disease, which is often severe, and therefore frequently use emergency departments for cardiac complaints. Additionally, complications from the devices are not uncommon, with 7.4 to 15% of pacemakers failing in the first year. [4] AICD complication rates, including inadvertent shocks, occur in up to 34% of patients with the device. [5]

Although the basic evaluation and treatment of patients with pacemakers or AICDs presenting with cardiac complaints is not substantially different from that of patients without the devices, a knowledge of the range of potential problems and complications and techniques for evaluating or inactivating pacemakers or AICDs is important for emergency physicians.

## BACKGROUND

The relationship between applied electricity and ventricular rhythms and arrhythmias has been understood since the late 1800s. [3] With the onset of cardiac monitoring techniques in the 1940s, the relationships between sudden death, cardiac syncope, ventricular fibrillation, and bradycardias began to be understood. [6]

The first pacemakers were developed by Zoll in the 1950s. [6] The units were transcutaneous and used primarily for Stokes-Adams disease (syncope secondary to bradycardia or asystole). These early units could only be used transiently and only in a hospital setting, as they created severe patient discomfort. [6] In 1958, the first long-term implanted pacemaker was used. [7] The indications for pacemaker use were rapidly expanded, as was the technology of the devices.

The first human defibrillation was performed intraoperatively in 1947 and the first transthoracic defibrillation in 1956. [8] Rapid defibrillation is now the standard of care for ventricular fibrillation, and its use has significantly increased survival of cardiac arrest. However, patients who survive cardiac arrest have a high risk of recurrent arrest, estimated at 22% to 60% in the first year. [9] [10]

AICDs were developed by Mirowski in the late 1960s, but they were not accepted by the medical community until the late 1970s. [3] In 1980, the first AICD was implanted in a human, followed by implantation in a series of patients [11] in whom an average of 52%

decrease in mortality was seen. [12] Between 1985 and 1990, more than 10,000 patients received AICDs, and the number continues to increase

## PACEMAKER CHARACTERISTICS

Several hundred types of pacemakers are in use today. The typical generator is a hermetically sealed device weighing from 30 to 130 g. [13] Modern power sources are almost exclusively lithium-based batteries, [14] which have the advantage of a slow, steady, predictable decay rate. Half-lives of lithium batteries range from 75 to 144 months. [14] The generator is connected to sensing and pacing electrodes that are placed in varying locations in the heart depending on the configuration of the pacemaker. Newer models are programmable for rate, output, sensitivity, refractory period, and modes of response, [13] and they can be reprogrammed radiotelemetrically after implantation.

Pacemakers are classified according to a standard code developed by the North American Society of Pacing and Electrophysiology/British Pacing and Electrophysiology Group (Table 12-1) . The first letter designates the chamber that actually receives the pacing current, whereas the second letter denotes which chamber the pacemaker uses to sense intrinsic cardiac electrical activity. The third letter denotes the pacemaker's response to sensed intrinsic electrical activity (usually inhibited). The fourth letter refers to the pacemaker's rate modulation and programmability, whereas the fifth letter describes antitachycardiac features of the pacemaker. In normal practice, only the first three letters are used to describe the pacemaker (e.g., VVI or DDD). [15]

**TABLE 12-1** -- North American Society of Pacing and Electrophysiology/British Pacing and Electrophysiology Group Generic Pacemaker Code (NBE Code)

| I | II | III | IV | V |
|---|---|---|---|---|
| Chamber Paced | Chamber Sensed | Response to Sensing | Rate Modulation and Programmability | Antitachycardia Features |
| 0--None | 0--None | 0--None | 0--None | 0--None |

| A--Atrium | A--Atrium | I--Inhibited | I--Inhibited | P--Antitachycardiac pacing |
|---|---|---|---|---|
| V--Ventricle | V--Ventricle | T--Triggered | M--Multiple | |
| D--Dual | D--Dual | D--Dual | C--Communicating | S--Shock |
| | | | R--Rate modulation | D--Dual |

Pacemaker wires are embedded in plastic catheters, and the terminal electrodes may be unipolar or bipolar. They travel from the generator unit to the heart via the venous system. The typical entry point is the subclavian or cephalic vein. The terminal electrodes are placed in the proper chambers, either the right ventricle, or both the right ventricle and atrium, under fluoroscopic guidance. Proper lead placement is checked by electrograms checking sensing and pacing thresholds. [16] The typical radiographic appearance of an implanted pacemaker is seen in Figure 12-1 .

The pacemaker rate is typically programmed between 60 and 80 beats/min. The pulse generator output is the product of volts, milliamperes, and the duration of stimulus, all of which may be preset or programmed. Sensing of intracardiac electrical activity is a combination of recognizing the characteristic waveforms of P waves or QRS complexes while also discriminating these from T waves or external interfering signals, such as muscle activity or movement. The pacing electrical stimulus is a triphasic wave consisting of an intrinsic deflection, far-field potential, and an injury current, which typically delivers a current of 0.1 to 20.0 mA for 2 msec at 15 V. [17]

Pacemakers have a reed switch, which may be closed by placing a magnet over the generator; this inactivates the sensing mechanism of the pacemaker, which then reverts to an asynchronous rate, termed the *magnet rate*. The magnet rate is usually, but not always, the same as the programmed rate.

## AICD CHARACTERISTICS

The AICD consists of a pulse generator with sensing mechanism, battery, and attached lead system with sensing and shocking abilities. The pulse generator and battery are contained in a hermetically sealed titanium case weighing 250 to 300 g. This case is approximately 10.8 × 2 × 7.6 cm, with variations depending on the manufacturer. The battery is typically a lithium battery with a life span of approximately 100 shocks, [18] [19] although a maximum life span of 22 months has been noted in one study. [9]

A variety of sensing and shocking leads are in use. Most current AICDs use two bipolar sensing electrodes that are secured in the epicardium, with two ventricular patches for shock delivery, which are usually placed anteriorly and posteriorly over the left ventricle (Figs. 12-2 (Figure Not Available) and 12-3) .

A new AICD with a single transvenous lead containing both sensing and shocking components is also in use (Fig. 12-4) . This model offers the advantage of obviating the need for cardiac surgery.

The electrical components of the AICD continuously monitor both rate and waveform [20] through separate sensing channels. Different models place a different emphasis on these channels, depending on the patient's underlying disease. The rate-detection channel determines if a preset limit, individualized for each patient, is exceeded. The second channel analyzes the morphology of the waveform of intrinsic cardiac electrical activity. Essentially, variance from a baseline is measured to determine if a shockable rhythm is present. Normal sinus rhythm has periods of isoelectric activity (the baseline), but ventricular fibrillation or sinusoidal tachydysrhythmias typically have a lack of these isoelectric segments.

A malignant ventricular tachydysrhythmia is usually present for 5 to 15 seconds before the preset rate and morphologic criteria are met. [18] At this time, the AICD charges its capacitor and delivers a shock of 25 J. This shock is synchronized in the case of ventricular tachycardia and unsynchronized in ventricular fibrillation. The time from the initiation of the arrhythmia to delivery of the shock is from 10 to 35 seconds.

If the arrhythmia persists after the first shock, subsequent shocks of 30 J are delivered, with each subsequent detection and shocking period lasting from 10 to 35 seconds. A total of four shocks are delivered if the rhythm is unchanged, after which the AICD does not deliver more shocks unless a subsequent change occurs in the rhythm that lasts more than 35 seconds. [5]

The AICD case is implanted in a subcutaneous pocket in the abdominal wall (Figs. 12-5 (Figure Not Available) and 12-6) . The wires are run through a subcutaneous tunnel to the chest. A variety of surgical approaches to the heart are used. [21] The ventricular patches are sutured to the epicardium or parietal pericardium in roughly anterior and posterior positions on the left ventricle, depending on the surgical approach. The sensing electrodes may be placed in either the left or right ventricle.

In those patients in whom the new transvenous lead is used, thoracotomy is not needed. In these patients the AICD case is still in the typical abdominal position, and a submuscular patch is placed in the chest wall.

AICDs may be inactivated by a magnet, either purposely or inadvertently. They may also be interrogated via a radiotelemetry device, which is a procedure that is normally only performed by the cardiologist.

# INDICATIONS FOR IMPLANTABLE DEVICE USE

Current indications for permanent pacemaker use include complete heart block, symptomatic type II second-degree block, second-degree block with episodic ventricular arrhythmias, sick sinus syndrome, symptomatic bradycardias with syncope or presyncope, hypersensitive carotid artery syndrome, type I block with infra-His bundle block, and certain subgroups of patients with triphasic and biphasic blocks at risk of developing sudden high-degree block. [16] [22]

The use of AICDs is generally limited to patients who are at high risk of sudden cardiac death from ventricular arrhythmias. Currently accepted indications are a documented episode of hemodynamically significant, sustained ventricular tachycardia or fibrillation; ventricular arrhythmia refractory to standard antiarrhythmic therapy as demonstrated electrophysiologically; persistent electrophysiologically inducible ventricular arrhythmia despite best available drug therapy; and recurrent syncope in a patient with electrophysiologically inducible ventricular arrhythmia in whom no effective drug is tolerated or available. [3] [18] [23]

Contraindications to AICD use are life expectancy of less than 6 months, New York Heart Association class IV heart failure, treatable causes of ventricular arrhythmias, or incessant or very frequent ventricular arrhythmias that result in rapid battery depletion.

# COMPLICATIONS OF PERMANENT PACEMAKERS

Complications are commonly seen with permanent pacemakers. Failure rates in the first year postimplantation range

**Figure 12-5** (Figure Not Available) Typical external appearance of AICD implanted in the abdominal wall. *(Courtesy of Lawrence B. Stack, M.D. From Munter DW, DeLacey WA: Automatic implantable cardioverter-defibrillators. Emerg Med Clin North Am 12:579-595, 1994. Used with permission.)*

from 7.4 to 15.0%, with most occurring within the first 30 days. [4] After this initial period, approximately 6% of pacemakers fail each year. [24]

Pacemaker failure can be categorized as failure to pace, failure to sense, failure to capture, inappropriate pacemaker rate, and other complications (e.g., vascular or infectious) (see Table 12-2) . Failure to sense is the most common problem, accounting for 32 to 57% of failure cases.

## Failure to Pace

This condition is characterized by the lack of production of pacemaker spikes despite the lack of intrinsic cardiac electrical activity or an intrinsic cardiac rate falling below the threshold for pacing. Causes of failure to pace include lead fracture or disconnection, battery depletion, component failure, and oversensing.

Lead fracture or disconnection may occur months to years after pacemaker implantation and may be due to inherent stress at the lead connection site. Blunt trauma may also cause lead fracture. [26] [27] [28]

Battery depletion is normally a gradual process and is usually detected before complete failure of the pacemaker.

| TABLE 12-2 -- Complications of Permanent Pacemaker Use |

| Low-amplitude intracardiac signal |
| **Failure to capture (pacemaker spikes but no subsequent cardiac activity)** |
| Lead dislodgement including perforation |
| Lead fracture |
| Lead disconnection |
| Poor lead position |
| Fibrosis around lead tip |

| |
|---|
| Battery depletion |
| Metabolic abnormalities |
| Medications |
| **Inappropriate pacemaker rate (runaway pacemaker)** |
| Pacemaker reentrant tachycardia |
| Resetting from external interference |
| Battery depletion |
| **Other** |
| Infections: pocket, wires |
| Lead displacement: cardiac perforation, tamponade, pericarditis, vascular perforation |
| Vascular complications: thrombosis, superior vena cava syndrome |
| Psychiatric: anxiety, panic attacks |

Patients who have not had regular follow-up may present with previously undetected

battery depletion.

Component failure may be due to a variety of external influences including blunt trauma, therapeutic radiation, electrocautery, transthoracic defibrillation, diathermy, electroshock therapy for depression, magnetic resonance imaging (MRI), and extracorporeal shock-wave lithotripsy.

Pacemakers may oversense, or misinterpret non-QRS complex electrical activity (e.g., P waves, T waves, muscular activity, or chest thumping). [25] If this activity is interpreted as a QRS complex, the ventricular spike will be inhibited. If, however, the pacemaker is dual chambered and the electrical activity is misinterpreted as a P wave, it will stimulate firing of the ventricular electrode, which can lead to overpacing. External stimuli can also be misinterpreted and lead to oversensing. This interference can include electrocautery, MRI, diathermy, transcutaneous electrical nerve stimulation (TENS), electroshock therapy, ultrasound dental scalers, static electricity, or vibration (e.g., from a tractor or helicopter).

## Failure to Sense

This condition is characterized by the presence of constant pacemaker spikes despite ongoing intrinsic cardiac electrical activity. Failure of the pacemaker to sense cardiac electrical activity can be due to lead dislodgement, lead fracture, normal development of fibrosis around the lead tip that occurs with time, battery depletion, external interference, or an intrinsically low-amplitude cardiac signal.

Lead dislodgement, the most common reason for failure to sense, can be due to an enlarged right ventricle, poor initial lead positioning, blunt trauma, or patient manipulation of the generator unit in the chest wall pocket (pacemaker twiddler's syndrome).

Fibrosis normally develops around the tip of the electrode, and this fibrosis can lead to abnormal sensing or higher required thresholds for pacing. [1]

Several cardiac and metabolic abnormalities cause the intrinsic cardiac electrical activity to be of lower than normal amplitude, causing undersensing of the QRS complexes.

## Failure to Capture

This condition is the appropriate presence and timing of pacemaker spikes, but without resultant cardiac activity. Reasons for failure to capture include lead dislodgement (e.g., myocardial perforation), lead fracture, lead disconnection, poor lead position, lead tip fibrosis, battery depletion, and metabolic abnormalities (e.g., hyperkalemia) or medications (e.g., lidocaine, flecainide) that make the myocardium less responsive to electrical impulses. Lead dislodgement is the most common reason for failure to capture. [25]

### Inappropriate Pacemaker Rate

This condition, also known as a *runaway pacemaker*, is a rare complication that is usually seen in dual-chamber pacemakers.  In dual-chamber pacers, it is caused by an endless loop reentry tachycardia, often initiated by a retrograde P wave. [41] In older, or single-chamber pacemakers, it can be due to component failure or battery depletion. [42] Component failure is rare, as almost all pacemakers have circuitry to prevent high discharge rates.

### Other Complications

Infections including localized skin or pocket infections, more complicated infections along the route of the wires, or endocarditis occur in 1 to 15% of patients. These infections are initially treated with broad-spectrum antibiotics against *Staphylococcus aureus*, but they often require removal of the pacemaker.

Lead displacement, in addition to causing failure to sense or capture, can cause injury to the myocardium including cardiac perforation with resultant tamponade or restrictive pericarditis,  and it is usually seen early after pacemaker implantation.

Fracture of the J-shaped retention wire within the lead can result in a protrusion of the wire outside the protective plastic coating. This protruding wire can then puncture the superior vena cava or right atrium resulting in bleeding or cardiac tamponade. [48] Figure 12-7 (Figure Not Available) illustrates this fracture.

Vascular complications include thrombosis or superior vena cava syndrome. Many pacemaker patients have a benign thrombosis of the upper arm or shoulder, but only about 2% have a serious thrombotic or embolic event. [45] Superior vena cava syndrome is a rare complication. [49]

Psychiatric complications include panic attacks and anxiety, which may prompt ED evaluation.

## COMPLICATIONS OF AICDs

The most common complication is the delivery of inappropriate shocks by the device when not indicated by a tachydysrhythmia. Up to 35% of AICD patients receive inappropriate

**Figure 12-7** (Figure Not Available) *A* and *B*, Appearance of fracture of atrial "J" retention wire. *A*, Radiographic appearance of fracture of atrial "J" retention wire. *B*, Diagram of fracture site. *(Courtesy of Telectronics Pacing Systems, Englewood, Colo.)*

shocks. [50] Causes of inappropriate shock delivery include misinterpretation of sinus tachycardia, atrial fibrillation, muscular activity (e.g., shivering), T waves, or extraneous sources (e.g., pacemaker spikes or vibrations) as a shockable tachydysrhythmia.

Likewise an unsustained tachydysrhythmia also may be shocked. Component failure, such as electrode failure or migration, may result in false sensing and resultant shocking. Pacemaker magnet testing has produced inappropriate shocks resulting in ventricular fibrillation.

Other reported long-term complications include interference with cardiac pacemakers, particularly after AICD discharge [54] [55] ; component failures, such as patch migration or distortion, [56] lead fracture, generator case rotation or fracture, and battery depletion; constrictive pericarditis and pericardial effusions,  cardiac fibrosis, and atrial or ventricular wall perforations after repeated shocks [59] [60] ; abdominal pocket infections [61] ; thrombosis and pulmonary embolism; erosion into the lung with hemoptysis [62] ; patient trauma sustained during falls after delivery of a shock, either due to the physical "jolt" of the shock [63] or to suspected postshock bradycardia and hypotension] ; and psychiatric disorders, such as adjustment disorder, panic attacks, or major depression.

The AICD may be inadvertently inactivated by any strong magnetic force including microwave ovens, industrial engines, metal detectors, magnets in speakers, refrigerator door magnets, bingo wands, and model airplane starters. [5] This inactivation is not normally noted until routine follow-up, but if the patient has a tachydysrhythmia, no shock will be delivered.

## EVALUATION OF PACEMAKER PATIENTS

Pacemaker patients presenting to the ED for any problem that may be associated with the device should have an evaluation that includes investigation of potential pacemaker malfunction.

**Historical Issues**

Pertinent information about the pacemaker unit should be obtained. The brand and manufacturer, type (NBE code), *implantation site, programmed rate, and any changes seen during follow-up at a pacemaker clinic should be noted. The time of implantation is important as certain types of complications such as lead failure, migration, or perforation typically occur within 3 months, whereas generator or battery failure usually occur later. [1]

Some medications, such as lidocaine or flecainide, can raise myocardial thresholds to pacing, [25] and their use should be queried.

Patient symptoms that may be related to pacemaker failure should be ascertained. Chest pain may be due to cardiac ischemia, but pacemaker complications such as cardiac perforation, pericarditis, or infection may also be the cause.

Recent trauma, especially to the chest or back, can cause failure of the generator unit, lead fracture, or lead displacement. Recent cardioversion or defibrillation, MRI, diathermy, lithotripsy, or electroconvulsive therapy for depression can have the same

effect.

Symptoms of decreased cerebral perfusion, such as syncope, near-syncope, or orthostatic light-headedness, may be an indication of pacemaker malfunctioning leading to bradycardias. Runaway pacemaker can also cause these symptoms as a result of low cardiac output during the tachycardic phase.

Palpitations are more typically due to intrinsic cardiac activity, but pacemaker failure to sense can cause an irregular rhythm due to inappropriate generation of pacer spikes, which may be perceived by the patient.

## Physical Examination

The patient should be examined for potential pacemaker complications. The head and neck should be inspected for venous engorgement that may be indicative of thrombosis or superior vena cava syndrome. [1]

The chest wall, and especially the pacemaker pocket, should be inspected and palpated for erythema, edema, tenderness, and location of the pacemaker generator. The initial course of the lead wires should also be palpated. If the generator unit is malrotated or in a position other than the original pacemaker pocket, this may be indicative of "pacemaker twiddler's syndrome" (i.e., purposeful or inadvertent manipulation by the patient), [38] [39] which can lead to lead dislodgement or disconnection.

The cardiac examination may be altered by the functioning of the pacemaker. A paradoxically split second heart sound is normal and is due to the origination of the pacemaker spike in the right ventricle. If the second heart sound is widely split, and widens more with inspiration, a left ventricular origin may be present due to cardiac perforation or lead migration. [1] A pericardial friction rub may be due to pericarditis, potentially from lead perforation. [46] A new murmur may be the result of infective endocarditis. [1]

## X-Ray

A chest radiograph should be obtained and compared to old films, preferably ones taken shortly after implantation. Location of the generator and battery type should be ascertained. Lithium batteries are seen as a single radiopaque portion of the generator unit, whereas older pacemakers have 4 to 5 button batteries. Location of the leads should be noted and migration should be looked for. Lead presence outside the myocardial shadow is indicative of perforation. The connection site at the generator unit should be examined for disconnection. The lead wires should be traced and examined for fracture, or J retention wire fractures.

## Electrocardiogram

The electrocardiogram (ECG) contains important information about pacemaker function and should be compared to old ECGs. An asynchronous mode pacemaker (i.e., VOO)

will have regular pacer spikes followed by QRS activity. A left bundle-branch pattern is normal, as the lead is usually in the right ventricle. Absence of pacer spikes in the asynchronous mode is termed *failure to pace*. Absence of a QRS complex after a pacer spike represents failure to capture. Some pacemakers have a programmed feature called hysteresis, in which the intrinsic rate below which pacing is triggered is somewhat lower than the resultant pacing rate. Hence the pause following a spontaneous QRS complex may be longer than an R-R interval at normal pace.

Pacemakers that sense intrinsic cardiac activity and are inhibited by same (i.e., VVI) should only generate pacer spikes if the patient's intrinsic rate falls below the programmed rate. In this case, pacer spikes followed by QRS complexes, again in a left bundle-branch pattern, should be noted. Failure to pace or capture may be seen. Pacer spikes occurring despite an intrinsic rate above the programmed rate represent failure to sense.

Dual chamber pacemakers (i.e., DDD) can have a variety of paced rhythms. [1] This includes the patient's intrinsic rhythm, atrial pacer spikes followed by a P wave and then an intrinsic QRS, or two pacer spikes sequentially followed by a P wave and then a QRS complex. Failure to pace, capture, or sense may again be noted.

The electrical axis of the pacer spike and paced QRS complex should be compared to old ECGs. A change of the pacer spike axis may be a sign of lead migration. [1] Normally, the paced QRS complex is a left bundle-branch pattern. A right bundle-branch pattern may be due to left ventricular lead placement, but a change from old ECGs from a left to a right bundle-branch pattern may be due to migration of the lead or perforation of the ventricular septum.

Paced rates that are higher than the programmed rate can be due to pacemaker-mediated tachycardia, a reentrant tachycardia normally seen only in dual-chambered pacemakers, [40] [41] or runaway pacemaker, normally seen only in older pacemaker models and due to battery depletion or component failure. [42] External electrical sources can mimic pacemaker spikes and be misinterpreted as an inappropriate pacing rate. [1]

Patients who are found to have failure to sense or failure to capture should undergo the basic evaluation outlined above; in addition, serum electrolyte assays should be performed to look for metabolic abnormalities. These patients and patients with infections, lead displacement, disconnection or fracture, or vascular complications will require cardiology consultation for intervention as determined by the etiology of the malfunction.

Patients who have failure to pace should undergo a

**Figure 12-8** Ring magnet.

**Figure 12-9** Typical location of pacemaker pocket in upper chest wall.

magnet test in the ED to rule out battery depletion or oversensing.

Patients with pacemaker-mediated tachycardia or runaway pacemaker need prompt cardiology evaluation, and those whose condition is unstable require acute intervention, as outlined below, in the ED.

### Use of a Magnet in Pacemaker Assessment

**Indications**

Magnet testing of a pacemaker is indicated to assess patients with "failure to pace" to assess for battery depletion, component failure, or oversensing. It is also indicated for pacemaker-mediated tachycardia or runaway pacemaker in an attempt to terminate the rhythm.

**Equipment and Setup**

Typically, a ring magnet (Fig. 12-8) is used for this procedure. Different brands of magnets are also available for specific pacemakers, but in almost all cases, a standard pacemaker ring magnet will suffice. The patient should undergo a baseline ECG. The patient should be on a cardiac monitor. Placement of a magnet on a pacemaker closes a reed switch and reverts the pacemaker to an asynchronous mode.

**Technique**

The location and orientation of the pacemaker generator should be ascertained by palpation. It is typically in the left or right upper chest wall (Fig. 12-9) . The magnet is placed directly over the pacemaker generator (Fig. 12-10) . A repeat ECG is obtained to compare to the baseline (Fig. 12-11 and 12-12) . Some brands of pacemakers have either a several-second delay or a series of 2 to 3 rapid pacer spikes before reverting to the asynchronous mode. [1] If the patient has an underlying bradycardia associated with failure to pace that is corrected by magnet placement, the magnet should be left over the generator. Likewise, if a pacemaker-mediated tachycardia or runaway pacemaker is reverted to a normal rate or rhythm, the magnet should be left in place pending consultation with a cardiologist.

**Complications**

Incorrect alignment of the magnet may cause only intermittent pacing in the asynchronous mode. Some pacemakers

**Figure 12-10** Application of ring magnet over pacemaker generator.

react erratically to a non-brand-specific magnet; if this is considered to be an issue, attempt to obtain a brand-specific magnet.

### Interpretation

In the case of failure to pace, three outcomes are possible: (1) The pacemaker will fire at its programmed rate (this is the expected outcome). In the case of failure to pace, this indicates that the pacemaker was oversensing and was inappropriately inhibited. The cause of the oversensing should then be investigated. (2) The pacer may not produce any spikes at all. This is indicative of component failure and requires cardiology consultation. (3) The pacemaker may produce spikes, but at a rate lower than the programmed rate, which is indicative of battery depletion; this also requires cardiology consultation.

## Management of Pacemaker-Mediated Tachycardia or Runaway Pacemaker

### Indications

These maneuvers are indicated for correction of an inappropriately high pacemaker rate.

### Equipment and Setup

IV access should be obtained and the patient should be placed on a cardiac monitor. A baseline ECG should be obtained. Because the definitive treatment often requires radiotelemetric reprogramming of the pacemaker, an immediate ("stat") cardiology consultation should be obtained. A ring magnet will be needed. A transcutaneous pacemaker unit with pads may be needed. If open lead disconnection is required, local anesthetic, sterile drapes, scalpel blade and handle, hemostats, and Mayo scissors or wire cutters will be needed as well as either a transcutaneous pacemaker or portable pacemaker unit with alligator clip.

### Technique

The initial procedure is to place a ring magnet over the pacer generator as described above. If the pacer then reverts to an asynchronous mode at the appropriate programmed rate, the magnet should be left in place.

If magnet placement has no effect, then isometric pectoral exercises should be attempted. [15] [40] This is done by having the patient place his hand from the same side as the pacemaker generator onto the opposite shoulder and push against the shoulder as long and as hard as possible. This creates rapid muscle activity in the pectoral muscle surrounding the pacemaker generator, which may be interpreted as ventricular activity and inhibit the pacemaker, [40] [41] terminating the reentrant tachycardia.

If this maneuver is unsuccessful and the patient's condition is stable, continue to monitor the patient and await cardiology consultation. If the patient's condition is unstable, the next maneuver is to attempt a standard chest *(precordial)* thump. [15] [40] This is performed by firmly striking the midsternum with a clenched fist from a distance of 30 to 38 cm. This procedure may be repeated once if needed. [40]

If the chest thump is unsuccessful, attach transcutaneous pacemaker pads anteriorly and posteriorly, and attach the leads to the transcutaneous pacemaker generator. Pace the patient at an initial output of 2 to 5 mA and a rate of 40 beats/min. [40] This will stimulate chest wall movement that may be interpreted as ventricular activity and inhibit the pacemaker, terminating the reentrant tachycardia. Unipolar DDD pacemakers are normally inhibited at a low output. Bipolar DDD pacemakers often need higher outputs of up to 10 to 20 mA. [40] If increasing the output is unsuccessful, raise the transcutaneous pacing rate slightly to attempt to deliver chest wall stimulation outside the pacemaker's particular ventricular refractory period. [40]

If these maneuvers are unsuccessful and the patient is hemodynamically unstable due to the pacer-induced tachycardia, the solution of last resort is to cut the pacer leads from the generator unit. The generator unit should be palpated to ascertain position and orientation. Apply transcutaneous pacemaker pads and connect them to the transcutaneous pacemaker. This is a precautionary measure, as cutting the leads may lead to profound bradycardia or asystole. A portable pacemaker generator should be available. Use povidone-iodine for sterile preparation of the site over the generator and drape with sterile drapes. Instill local anesthesia in the skin and subcutaneous tissue overlying the generator in the area of the lead connections. Make a skin incision with a scalpel, and expose the lead wires with blunt dissection. Alternatively, make an incision through the previous scar and remove the pacemaker unit. [42] Cut the lead wires close to the generator using Mayo scissors or wire cutters. At this point, the patient may require transcutaneous pacing. An alternate is to insert a needle into the cathode (negative) lead wire (this is the only wire on unipolar models, and it is identified on bipolar units either by marking or by a white band). [42] Connect an alligator clip to the needle, and connect the alligator clip to the negative terminal of the portable pacemaker generator. Ground the positive terminal via an alligator clip to the subcutaneous tissue of the incision, and pace the patient using the portable generator. [42]

## Complications

Incorrect alignment of the magnet may cause pacing only intermittently in the asynchronous mode. Some pacemakers will react erratically to a non-brand-specific magnet; if this is a problem, attempt to obtain a brand-specific magnet. There are no potential complications from isometric pectoral muscle exercise. Chest thumps can result in sternal or rib fractures, myocardial contusion, pulmonary contusion, extrasystolic

complexes, or ventricular tachydysrhythmias. [40] Transcutaneous pacing to stimulate chest wall movement is normally uncomfortable for the patient and can also result in diaphragmatic or arm muscle stimulation as well. Open disconnection of the pacemaker

lead wires can be complicated by unanticipated bleeding, difficulty exposing the generator unit, and subsequent infection. A more common complication is the termination of the paced rhythm resulting in a profound bradycardia or asystole that requires ongoing transcutaneous or portable generator pacing. [42]

## Interpretation

Correction of the pacer-induced tachycardia by lead disconnection only is generally indicative of component failure or severe battery depletion, whereas termination by noninvasive procedures is more indicative of a pacemaker-induced endless loop reentrant tachycardia

# EVALUATION OF AICD PATIENTS

Patients with an AICD who present to the ED can have noncardiac complaints unrelated to the AICD, cardiac complaints, or AICD-related problems, including AICD shocks. The evaluation should focus on potential AICD problems.

## Historical Issues

Patients with AICDs have severe underlying cardiac disease, and will often present with cardiac chest pain, shortness of breath, or congestive heart failure. Potential AICD complications such as pericarditis, pericardial effusion, cardiac fibrosis, atrial or ventricular perforation, and infections of the wires or leads can all present with chest pain. Mortality in AICD patients is typically due to their underlying disease, and any complaints of chest pain must be pursued aggressively.

Generator pocket infections or wound infections will produce complaints of pain and fever.

The most common AICD-related complaint in patients presenting to the ED is that of one or more AICD shocks. Patients describe the shock as a feeling of being kicked or punched in the chest. [69] [70] The number of shocks received should be ascertained. Associated symptoms of syncope or near-syncope indicate a probable tachydysrhythmia and appropriate shock. Many patients fall down when they experience an AICD shock, and the presence of any fall-related trauma should be queried.

## Physical Examination

Inspection and palpation of the abdominal pocket and subcutaneous tunnel should be done for signs of infection. Heart and lung sounds should be auscultated. A pericardial rub is indicative of pericardial fluid, which may be a result of pericarditis from the AICD. The patient should be examined for any signs of trauma if they sustained a fall.

## X-Ray

A chest radiograph is generally not helpful, but one should be obtained and compared to old films to look for electrode fracture, displacement of sensing electrodes, and patch migration or distortion.

## Electrocardiograms

An ECG should be obtained. Immediately after an AICD shock, the ECG often shows abnormalities such as ST-segment elevations or depressions. [60] [71] If these changes are due solely to the shock, they will resolve within 15 minutes. Otherwise, the ECG should be examined and compared to old studies for evidence of ischemia.

## Use of a Magnet for AICD Inactivation

The patient who is experiencing inappropriate AICD discharges in the ED can be treated by magnet inactivation of the device similar to the approach described earlier for the pacemaker patient.

### Technique

The method for inactivating an AICD device is outlined in Table 12-3 (Table Not Available) . The orientation of the device in the abdominal pocket should be determined, with the lead connections normally cephalad. A ring magnet is then placed over the corner adjacent to the lead connections (usually the upper righthand corner of the device) (Fig. 12-13) . A series of beeping tones will sound, which correspond to the sensed QRS complexes. In the absence of organized QRS activity, random beeps will sound. [69] When the magnet is left in place for 30 seconds, a continuous beep is heard. This indicates that the AICD is inactivated. The magnet should then be removed, and the AICD will remain inactivated. The AICD may be reactivated by applying the magnet for 30 seconds and removing it when the steady beep changes to intermittent beeping.

## Clinical Follow-up

The AICD patient who has component failure, such as patch migration or lead fracture or dislodgement; infection; vascular complications, such as thrombosis or perforation; or cardiac complications, such as perforation or pericarditis, require cardiology consultation for admission.

The AICD patient who received a single shock and had prodromal symptoms indicative of low cardiac output should be evaluated for myocardial infarction, electrolyte imbalance,

| TABLE 12-3 -- Method for Inactivation of AICD |
|:---|

| (Not Available) |

or drug toxicity, as well as for any sustained trauma. If findings of this evaluation are normal, the patient is usually released home after discussion with the cardiologist. [5]

The patient who received a single shock without related symptoms consistent with a ventricular tachydysrhythmia requires a more extensive evaluation including cardiac monitoring, determination of drug levels as appropriate, and electrolyte level measurement. [69] [70] [72] If the ED evaluation is normal, patients require cardiology consultation. The cardiologist normally interrogates the AICD using either phonogram or telemetry units. The decision to admit or release the patient with potential alterations of antiarrhythmic drug therapy is made based on the results of this testing.

Patients whose condition is unstable, who report more than one shock in succession or more than two single shocks in a 1-week period, or who have evidence of ischemia, electrolyte imbalance, or drug toxicity require admission to a monitored setting for further evaluation and continued monitoring.

## THE PACEMAKER/AICD PATIENT IN CARDIAC ARREST

Patients with pacemakers in cardiac arrest may require defibrillation or cardioversion, depending on their presentation. Although most pacemakers have circuitry that protects them from high current flows, a variety of pacemaker-related problems can develop from defibrillation or cardioversion. These include damage to circuitry resulting in complete destruction, decrease in output, or runaway pacing; acute or chronic increases in the pacing threshold, which is normally temporary; undersensing lasting up to 10 days; reprogramming; resetting to a different mode, usually asynchronous; lead displacement; and myocardial thermal or electrical burns at the electrode-myocardium interface leading to ventricular fibrillation. [29]

Due to these potential complications, Barold and colleagues have suggested guidelines for defibrillation and cardioversion in pacemaker patients. [29] The first of these is the use of anterior-posterior paddle position, if possible, preferably with specific anterior and posterior paddles. When this is not possible, the paddles should be placed along a line perpendicular to the line between the pulse generator and the tip of the ventricular lead. For a patient with a pacemaker generator in the left upper chest wall, the appropriate paddle placement would be left lateral chest wall and right midsternal border. For a patient with a pacemaker generator in the right upper chest wall, the appropriate paddle placement would be left upper chest wall and right lower chest wall. Second, the

paddles should be placed at least 10 cm from the pulse generator or lead. Third, because of the potential for damage to the pacemaker or leads, a transcutaneous pacemaker and pads should be readily available if needed, and standby cardiology consultation should be arranged in case emergent reprogramming is needed. Fourth, the patient must be admitted to the hospital and pacemaker functioning must be monitored carefully with repeated threshold testing.

Because of the lower current used by AICDs, the possibility of pacemaker damage from AICD discharge in patients with both is remote. [29]

The AICD patient who is in cardiopulmonary arrest may be managed in the same manner as patients without the device, with minor modifications. Cardiopulmonary resuscitation (CPR) and transthoracic defibrillation will not harm the AICD. [69] The AICD may spontaneously discharge without warning if the patient's rhythm meets the preset criteria for shocking. In the case of an AICD shock, medical personnel performing CPR may experience a mild electrical shock, [73] but to date no reports of injury to medical personnel from such a shock have been noted.

Some authors recommend leaving the AICD activated during cardiopulmonary arrest, [69] allowing it to discharge up to the maximum of four times allowed by the circuitry; but deactivation may be necessary to alleviate fears of medical personnel, to avoid AICD shock-induced arrhythmias, or if temporary cardiac pacing is needed. [5]

Defibrillation does not harm the device or circuitry, and may be performed with the usual technique, although a theoretical possibility exists that the epicardial patches can shield the myocardium from the delivered energy. For this reason, paddle placement over the apex and right sternum may be indicated for AICD patients with anterior and posterior myocardial patches, with anterior and posterior paddle placement in AICD patients with a single patch over the cardiac apex.

## CONCLUSION

Many patients have implanted pacemakers or AICDs. These patients have underlying cardiac disease and may present to the ED with a variety of complaints. Complications associated with these devices are not uncommon. The evaluation of these patients must be directed toward the potential complications. Pacemaker function may be evaluated by ECG and magnet testing, but most problems will require cardiology consultation and intervention. Runaway pacemaker represents a true emergency and must be dealt with expeditiously. AICD complications can be initially evaluated in the ED, but they normally require specialized interrogation devices to analyze the problem. Patients with pacemakers or AICDs in cardiopulmonary arrest require modifications of standard paddle placement for defibrillation or cardioversion, and if an AICD is present, it may need to be deactivated with a magnet.

# Chapter 14 - Emergency Transcutaneous Cardiac Pacing

**Scott A. Syverud**

**Jerris R. Hedges**

Transcutaneous cardiac pacing (TCP) is a rapid, minimally invasive method of treating severe bradycardias and asystole. Electrodes are applied to the skin of the anterior and posterior chest walls, and pacing is initiated with a portable pulse generator. In an emergency setting, this pacing technique is faster and easier to initiate than transvenous pacing. Pulse generators are sufficiently portable to be used in emergency departments, hospital wards, intensive care units, and mobile paramedic vehicles.

In 1872, Duchenne de Boulogne reported a successful resuscitation of a child by attaching 1 electrode to a limb while a second electrode was rhythmically touched to the precordium of the thorax. [1] Successful overdrive pacing of the human heart, using a precordial electrode, was reported by VonZiemssen in 1882. [2]

In 1952, Zoll introduced the first practical means of TCP. Using a ground electrode attached to the skin and a subcutaneous needle electrode over the precordium, he reported the successful resuscitation of 2 patients in ventricular standstill. [3] One patient was paced for 5 days and subsequently was discharged from the hospital. Zoll later introduced a machine that delivered impulses lasting 2 msec through 3-cm-diameter metal paddles pressed firmly against the anterior chest wall. This device was the first commercial transcutaneous cardiac pacemaker. During the 1950s, Zoll and Leatham demonstrated the effectiveness of TCP in patients with bradycardia and asystole. [4] [5] [6] [7] Leatham used larger electrodes (4 × 6 cm) and a longer pulse duration (20 msec) to successfully pace 2 patients with bradydysrhythmias. [7]

Until the late 1950s, TCP was the only clinically accepted method of cardiac pacing. The original technique using bare metal electrodes had adverse effects, including local tissue burns, muscle contraction, and severe pain. [3] [7] With the development of the first implantable pacemakers from 1958 through 1960 and the improvement of transvenous electrodes during the early 1960s, TCP was rapidly discarded. [8]

Refinements in electrode size and pulse characteristics have led to the reintroduction of TCP into clinical practice. [9] [10] Increasing the pulse duration from 2 to 20 msec or longer was found to decrease the current output required for cardiac capture. [11] [12] Longer impulse durations also make the induction of ventricular fibrillation less likely. [11] Larger surface area electrodes (8-cm diameter) decrease the current density at the underlying skin and therefore decrease pain and the possibility of tissue burns. [9]

## INDICATIONS AND CONTRAINDICATIONS

General indications for cardiac pacing are discussed in Chapter 13 . TCP is technically

the fastest and easiest method of emergency pacing. This technique is useful for initial stabilization of the patient in the emergency department who requires emergency pacing while arrangements for transvenous pacemaker insertion are being made. The use of the equipment is readily mastered, and the procedure is fast and minimally invasive. [10] [13] Refinements in equipment have made TCP the emergency pacing procedure of choice. TCP also is gaining widespread out-of-hospital use in helicopter ambulance programs and inhospital use in the cardiac catheterization laboratory, operating room, intensive care unit, and on general medical floors. [14] [15] [16] The technique may be preferable to transvenous pacing in patients who have received thrombolytic agents. No central venous puncture, with the attendant risk of hemorrhage, is required. Limited experience suggests that TCP also may be useful in the treatment of refractory tachydysrhythmias by overdrive pacing.  Although small pediatric electrodes for TCP have been developed, experience with pediatric TCP has been limited.

TCP is indicated for the treatment of hemodynamically significant bradydysrhythmias that have not responded to atropine therapy. *Hemodynamically significant* implies hypotension, anginal chest pain, pulmonary edema, or evidence of decreased cerebral perfusion. This technique is a *temporary* technique that is indicated for short intervals as a bridge until transvenous pacing can be initiated or until the underlying cause of the bradyarrhythmia (e.g., hyperkalemia, [13] drug overdose [24] ) can be reversed. Although often unsuccessful, TCP may be attempted in the treatment of asystolic cardiac arrest. In this setting the technique is efficacious only if used early after arrest onset (generally within 10 minutes). TCP is not indicated for treatment of prolonged arrest victims with a final morbid rhythm of asystole.

Delay from the onset of arrest to the initiation of pacing

is a major problem that limits the usefulness of TCP in out-of-hospital care. Hedges and colleagues reported that everyday availability of pacing increased the number of patients who received pacing within 10 minutes of hemodynamic decompensation and increased long-term patient survival as well. [28] Out-of-hospital pacing may be most useful in treatment of the patient with a hemodynamically significant bradycardia who has not yet progressed to cardiac arrest (e.g., heart block in the setting of acute myocardial infarction) or in the patient who arrests after the arrival of out-of-hospital providers. [27] [28]

In conscious patients with hemodynamically stable bradycardias, TCP may not be necessary. It is reasonable to attach electrodes to such patients and to leave the pacemaker in standby mode against the possibility of hemodynamic deterioration while further efforts at treatment of the patient's underlying disorder are being made. This approach has been used successfully in patients with new heart block in the setting of cardiac ischemia. [26] Generally when a transvenous pacemaker becomes available, transvenous pacing is preferred because of better patient tolerance.

## EQUIPMENT

Few medical product lines have changed as rapidly as commercial transcutaneous pacemakers. Patent controversy, corporate acquisitions, and rapid product evolution

have all contributed to this rapid change. [34] Of 8 commercial transcutaneous pacemakers reviewed in a 1988 product review, [35] 4 are no longer available. Several manufacturers no longer produce transcutaneous pacemakers or have gone out of business.

Despite this instability in the marketplace, transcutaneous pacemakers are now standard equipment in most emergency departments and are rapidly spreading to other inhospital and out-of-hospital care settings. The pacemakers introduced in the early 1980s tended to be asynchronous devices with a limited selection of rate and output parameters. Units introduced more recently have demand mode pacing and more output options and are more likely to be combined with a defibrillator in a single unit. Combined defibrillator-pacers offer advantages in both cost and ease and rapidity of use when compared with stand-alone devices. An example of 1 combined unit is shown in Fig. 14-1 (Figure Not Available) . A full-featured stand-alone pacemaker is illustrated in Fig. 14-2 (Figure Not Available) .

All transcutaneous pacemakers have similar basic features. Most allow operation in either a fixed rate (asynchronous) or a demand mode. Most allow rate selection in a range from 30 to 200 beats/min. Current output is usually adjustable from 0 to 150 mA. If an electrocardiography (ECG) monitor is not an integral part of the unit, *an output adapter to a separate monitor is required* to "blank" the large electrical spike from the pacemaker impulse and allow interpretation of the much smaller ECG complex. Without blanking protection, the standard ECG machine is swamped by the pacemaker spike and is uninterpretable. This could be disastrous, because the large pacing artifacts *can mask treatable ventricular fibrillation* (Fig. 14-3) . Pulse durations on available units vary from 20 to 40 msec and are not adjustable by the operator.

Two sets of patient electrodes are usually required for

**Figure 14-1** (Figure Not Available) Combined defibrillator-transcutaneous pacemaker unit (Zoll-PD). The unit defibrillates through standard hand-held paddles and has additional cable connections for electrocardiograph monitoring electrodes and for pacing electrodes. *(Courtesy of ZMI Corporation, Cambridge, Mass.)*

operation of the device. One set of standard ECG electrodes is used for monitoring. The much larger pacing electrodes deliver electrical impulses through an 8-cm-diameter conducting surface. One pacing electrode is placed over the mid-dorsal spine, and the other is placed over the left anterior chest. The posterior electrode serves as the ground.

One currently marketed combined defibrillator-pacemaker (Medac ALS System 4) uses a single set of electrodes for ECG monitoring, pacing, and defibrillation. Although this approach makes use of the device simpler, its clinical utility remains to be proved. Because the impedance characteristics of the ideal pacing electrode differ from those of the ideal ECG and defibrillation electrode, this approach may not prove to be ideal.

## TECHNIQUE

**Pad Placement**

The pacing electrodes are applied as shown in Figure 14-4 (Figure Not Available) and are attached to the instrument cable. The anterior electrode (cathode, or negative electrode) is placed as close as possible to the point of maximal impulse on the left anterior chest wall. This 8-cm-diameter electrode adheres to the skin and has a large surface area for electrical contact. The second electrode is placed directly posterior to the anterior electrode. Failure to capture may be due to misplacement of the electrodes, and failure to pace may be rectified with a small change in anterior electrode position. Electrocardiogram electrodes are placed on the chest wall and connected to the instrument cable. Some physicians prophylactically apply pacing electrodes to all critically ill patients with bradycardia to facilitate immediate TCP should decompensation occur.

**Figure 14-2** (Figure Not Available) "Stand alone" transcutaneous pacemaker (Zoll NTP). This unit has a built-in monitor and strip chart recorder. *(Courtesy of ZMI Corporation, Cambridge, Mass.)*

There is little risk of electrical injury to health care providers during TCP. Power delivered during each impulse is less than 1/1000 of that delivered during defibrillation. [36] Chest compressions (cardiopulmonary resuscitation) can be administered directly over the insulated electrodes while pacing. [29] Inadvertent contact with the active pacing surface results only in a mild shock.

**Pacing Bradycardic Rhythms**

To initiate TCP, the pacing electrodes are applied, and the device is activated. In the setting of bradyasystolic arrest, it is reasonable to turn the stimulating current to maximal output and then decrease the output as appropriate after capture is achieved. In a patient who has a hemodynamically compromising bradycardia but is not in cardiac arrest, the operator should slowly increase the output from the minimal setting until capture is achieved. Rate and output selections are adjustable (Fig. 14-5) . Generally a heart rate of 60 to 70 beats/min will maintain an adequate blood pressure (by blood pressure cuff or arterial catheter) or the desired degree of mentation.

Assessment of electrical capture can be made by monitoring the ECG on the filtered monitor of the pacing unit (Fig. 14-6) . Ideally, pacing should be continued at an output level just above the threshold of initial electrical capture. One study in 16 normal male volunteers who were paced without sedation noted cardiac capture at a mean current of 54 mA (range, 42 to 60 mA). [37] Most subjects could tolerate pacing at their capture threshold; only 1 subject required discontinuation of pacing at 60 mA because of intolerable pain. Heller and associates compared subjective pain perception and capture thresholds in 10 volunteers paced with 5 different transcutaneous pacers. [38] Capture rates (40 to 80%), thresholds (66.5 to 104 mA), and subjective discomfort varied from pacemaker to pacemaker.

Failure to capture with TCP may be related to electrode placement or patient size. Patients with barrel-shaped chests and large amounts of intrathoracic air conduct

electricity poorly and may prove refractory to capture. A recent thoracotomy has been found to nearly double the pacing threshold. [39] A large pericardial effusion or tamponade also will increase the output required for capture. [40] Failure to electrically capture with a transcutaneous device in these settings is an indication to consider immediate transvenous pacer placement.

Patients who are conscious or who regain consciousness during TCP will experience discomfort because of muscle contraction. [26] [37] [38] Analgesia with incremental doses of an opioid agent, sedation with a benzodiazepine compound, or both, will make this discomfort tolerable until transvenous pacing can be instituted.

**Overdrive Pacing**

Overdrive pacing [17] [18] [19] [20] [21] of ventricular tachycardia or paroxysmal supraventricular tachycardia is performed in patients who are stable enough to tolerate the brief delay associated with the necessary preparation for this technique. The patient is sedated as above, pacing and monitoring electrode pads are placed in the standard position as detailed earlier, and brief trains (6 to 10 beats) of asynchronous pacing are applied. The pacer rate must be set approximately 20 to 60 pulses/min greater than the dysrhythmia rate. [41] Generally, an impulse rate of 200 pulses/min is used for ventricular tachycardias (rate generally 150 to 180 beats/min), and a rate of 240 to 280 pulses/min is used for paroxysmal supraventricular tachycardias (rate commonly 200 to 250 beats/min).

For many commercial devices, the maximum device rate achievable is 120 pulses/min, thus prohibiting use of TCP for overdrive pacing. Interestingly, Altamura and colleagues have reported some success with "underdrive" pacing (i.e., TCP at a rate less than the tachydysrhythmia), although underdrive pacing seems less effective than the overdrive technique. [19]

Usually a current output considerably above the ventricular capture threshold is chosen to ensure that a wide area of myocardium is simultaneously depolarized. Generally a current output of 120 mA is used. After each train of impulses, the device is turned off, and the patient's cardiac rhythm is monitored. Generally no more than 3 trains of impulses are required. This technique may be combined with pharmacologic therapy.

Because rhythm acceleration is possible during overdrive pacing, it is essential that full resuscitation equipment, including a defibrillator, be available at the bedside.

## COMPLICATIONS

The major potential complication of TCP is *failure to recognize the presence of underlying treatable ventricular fibrillation*. This complication is primarily due to the size of the pacing artifact in the ECG screen, a technical problem inherent in systems without appropriate dampening circuitry.

A theoretical complication of TCP is the induction of dysrhythmias. In animal models

using epicardial electrodes, the threshold current required to induce ventricular fibrillation decreases as electrical impulse duration increases. At a 10-msec impulse duration, ventricular fibrillation can be induced with currents as low as 25 mA delivered through epicardial electrodes. [11] Because TCP impulses are of even longer duration (20 msec) and of higher current (50 to 200 mA), there has been concern about possible induction of ventricular fibrillation during TCP. Studies of fibrillation thresholds using large *precordial* electrodes have shown the relationship of threshold to impulse duration to be the opposite of that seen with *epicardial* electrodes. With *cutaneous* precordial electrodes, the current required to induce ventricular fibrillation *increases* as pulse duration *increases.* [12] The apparent paradox may be explained by the differing nature of the electrodes. Epicardial electrodes are localized over a small area of the myocardium, whereas transcutaneous

electrodes deliver a broad electrical charge to the myocardium as a whole. The implication is that longer impulse durations, although more dangerous with internal pacing, seem to decrease the chance of inducing ventricular fibrillation with TCP. Nonetheless, asynchronous TCP for tachydysrhythmias has been associated with rhythm acceleration and development of ventricular fibrillation. [19]

Experience with prolonged TCP in humans has not been extensive. Zoll and colleagues reported 25 humans paced for up to 108 hours with impulses of 20-msec duration. [6] Pacer-induced dysrhythmias did not occur. Leatham and associates paced 1 patient for 68 hours with impulses of 20-msec duration. [7] The patient died 2 days after pacing was discontinued. Pathologic examination revealed no evidence of pacer-induced myocardial damage. Madsen and colleagues paced 10 healthy volunteers at threshold for 30 minutes and found no enzyme or echocardiographic abnormalities. [42]

Studies of repetitive direct current countershocks in dogs have induced tissue damage with energy levels that are 1000 times greater than those required to pace the heart transcutaneously. In a canine study, 10 animals with chronic heart block that were paced for 60 minutes (20-msec duration at 80 beats/min with 8-cm-diameter cutaneous electrodes) did not develop pacer-related dysrhythmias. Serial cardiograms and cardiac enzymes revealed no evidence of ischemia or infarction. [43] Examination of the canine hearts after the dogs were sacrificed 72 hours after pacing did not reveal clinically significant myocardial damage. [44] A single primate paced for 1 hour with 20-msec impulses of 400 mA similarly had no evidence of tissue damage at autopsy and at microscopic examination after sacrifice 24 hours later. [45] Based on these studies, TCP appears unlikely to produce cardiac injury with short-term use in humans.

Soft tissue discomfort with the potential for injury may still occur with current transcutaneous pacemakers. One study with the Zoll transcutaneous pacemaker found only 2 of 30 subjects (patients and volunteers) who were paced while conscious required discontinuation of pacing owing to discomfort. [37] Most reported the discomfort as "mild or moderate and easily tolerable." Sedation would presumably improve a conscious patient's ability to tolerate TCP. Nonetheless, prolonged use may still induce local cutaneous injury; Pride and McKinley reported one 7-week-old child who was paced for 45 hours without a pad change and who developed third-degree burns.

## CONCLUSIONS

Devices that pace the heart have been available for clinical use since 1952. Technologic improvements have minimized the complications associated with earlier use of the transcutaneous route and have enabled the reapplication of this relatively old pacing technique to a selected subset of cardiac emergencies. The introduction of combined defibrillator-pacemakers promises to make pacing more available in out-of-hospital and health care settings. Although the technique is still not universally available, it is rapidly becoming the standard of care for resuscitation protocols and equipment. Pacing instituted earlier in the course of bradycardiac rhythms, including the out-of-hospital phase of care, may improve the poor survivial rate currently associated with these rhythms.

# Chapter 15 - Pericardiocentesis and Intracardiac Injections

**Richard J. Harper, Michael L. Callaham**

## Pericardiocentesis

Pericardiotomy under direct vision was first done in 1815, and in 1840, the first blind approach using a trocar was carried out successfully on a patient with tamponade from malignancy. [1] By the end of the 19th century, the trocar-and-cannula method of pericardiocentesis was commonly used. The subxiphoid approach was first described in 1911.

Blind, electrocardiography (ECG)-assisted pericardiocentesis has a significant morbidity rate, reportedly as high as 15 to 20%. [2] [3] For this reason ultrasound diagnosis of pericardial effusion with fluoroscopic or ultrasound guidance has become the norm for *elective* pericardiocentesis because of its lower (0.5 to 3.7%) [4] [5] incidence of complications. The ECG-assisted blind pericardiocentesis technique remains the standard procedure for truly *emergent* pericardiocentesis when a lengthy delay may be associated with obtaining and organizing ultrasound or fluoroscopic assistance.

### CAUSES OF PERICARDIAL EFFUSION AND TAMPONADE

The medical literature concerning pericardiocentesis tends to address two distinct categories of pericardial fluid collection: acute hemopericardium (largely secondary to trauma) and pericardial effusion from other causes. This separation is not entirely artificial, as these two clinical entities are quite different in their time course, etiology, and treatment.

#### Acute Hemopericardium

Acute hemopericardium has several causes, including coagulopathies, cardiovascular catastrophes, and acute injury resulting from either blunt or penetrating trauma. All of these causes result in rapid accumulation of whole blood in the pericardial sac. The fluid accumulates too fast for the relatively inelastic pericardial sac to stretch and accommodate the fluid. The result is cardiac tamponade produced by small fluid volumes and with an essentially normal pericardial size.

#### Penetrating Trauma

Traumatic tamponade due to penetrating trauma may result from obvious external injury such as knife or gunshot wounds, or it may be insidious, as seen with iatrogenic cardiac perforation during cardiac or vascular procedures.

In external penetrating trauma, tamponade is most commonly the result of a stab wound

to the heart, [6] presumably because the pericardium seals itself after a stab wound but cannot do so after gunshot wounds. [6] [7] Approximately 80 to 90% of stab wounds to the heart demonstrate tamponade, [6] [8] compared with 20% of gunshot wounds. Larger pericardial wounds from gunshots generally drain into the pleural space and produce a hemothorax. [9] Cardiac tamponade is often suspected with anterior chest wounds, but it is imperative to remember that any penetrating wound of the lateral chest, back, or upper abdomen also may involve the heart.

Iatrogenic causes of cardiac tamponade are relatively uncommon but well-known complications of invasive or diagnostic procedures. Pacemaker insertion (either transthoracic or transvenous) and cardiac catheterization, including valvuloplasty and angioplasty, are two of the main causes, resulting in tamponade when cardiac chambers or coronary vessels are inadvertently penetrated. [10] [11] [12] Such penetration of vascular structures is common during transthoracic pacemaker placement. [13] Tamponade is also seen as a complication after cardiac surgery, although it is usually anticipated, and

mediastinal or pericardial drainage helps to control and prevent it. [10] [14] Pericardiocentesis itself can cause tamponade by lacerating myocardium or coronary vessels. [15] [16]

Cardiac tamponade may result from perforation of the right atrium or, less commonly, of the right ventricle or superior vena cava by a central venous pressure (CVP) catheter or subclavian hemodialysis catheter. [17] This event is usually not diagnosed early and is therefore often fatal. [18] Perforation may occur during placement or, more commonly, 1 to 2 days later, when the catheter erodes through tissue, particularly if a catheter made of stiff material is used or when the left internal jugular vein approach is used. [19] Tamponade from CVP line placement is seldom seen in the emergency department but must always be considered when there is sudden decompensation in a patient with a CVP line in place. Tamponade should always be considered when a patient deteriorates hemodynamically after an invasive diagnostic or therapeutic procedure involving the heart.

**Blunt Trauma**

Blunt trauma may cause hemopericardium. Usually it occurs in the presence of a major chest injury with associated bruises or rib and sternal fractures. Cases have been reported, however, in which tamponade occurred in blunt trauma with no obvious signs of injury to the thorax. [20] Such incidents may be more common than is clinically recognized, judging by the reports of constrictive pericarditis and pericardial defects found months to years later in trauma patients who were not originally noted to have effusion. Pericardial effusion due to blunt trauma may also be a late finding, becoming symptomatic 12 to 15 days after trauma. [21]

Severe deceleration injury may cause tamponade as a result of aortic dissection. This appears to be an uncommon development, with two case series reporting tamponade in 3.6% (1 of 28 patients) and 2.3% (1 of 43 patients) of victims of aortic injury. [22]

Theoretically, cardiopulmonary resuscitation (CPR) can cause pericardial effusion secondary to the blunt trauma of chest compressions, broken ribs, or intracardiac injections. Early studies reported pericardial effusion in 1 to 3% of CPR survivors. [23] Echocardiographic studies showed small cardiac effusions (but not tamponade) in 12% of survivors, only 4% of whom had received intracardiac injections. [24] Thus, although case reports of tamponade exist, [25] [26] it would appear that CPR and intracardiac drug injections are unlikely to cause significant effusion, much less tamponade.

**Nontraumatic Hemopericardium**

Nontraumatic but acute hemopericardium caused by a bleeding diathesis, aortic dissection and ventricular rupture behaves much like traumatic tamponade because of its acute nature. These types of hemopericardium are less obvious in etiology than hemopericardium caused by external trauma.

Bleeding diathesis may cause spontaneous bleeding into the pericardial sac. The incidence of spontaneous pericardial tamponade in anticoagulated patients has been reported to range from 2.5 to 11%. [10] [27] Thrombolytic therapy has also been implicated in tamponade secondary to bleeding diathesis. Among 392 patients, only 4 (1%), all with large anterior myocardial infarctions, developed tamponade secondary to hemopericardium without ventricular rupture. [28]

A dissection of the ascending aorta may extend around the base of the aorta into the pericardial sac, causing dramatic, rapid, and often fatal tamponade. This pathologic abnormality may be due to conditions such as syphilis, Marfan syndrome, or atherosclerosis. Infection may create pseudoaneurysms of the aorta, which also can present as tamponade. [29]

Ventricular rupture after myocardial infarction is a common source of acute hemopericardium. Although the prognosis is often grim, survival is possible with prompt recognition and definitive treatment. [30] [31]

**Nonhemorrhagic Effusions**

The etiology of nonhemorrhagic pericardial effusions determines the aggressiveness, type, and speed of treatment required. Patients with nonhemorrhagic etiologies usually accumulate effusions slowly, which allows the pericardium to stretch and accommodate up to 2000 mL of fluid. [32] This slower accumulation, often over weeks to months, means that even in a moderately hypotensive patient, more time may be available for evaluation and treatment. [33] [34] In many cases of small nonhemorrhagic effusion, tamponade does not occur, and the effusion may resolve with treatment of the underlying disease or may be managed successfully by elective pericardiocentesis.

Many disease processes, ranging from the common to the rare (Table 15-1) , can cause pericardial effusion. The cause of nonhemorrhagic tamponade may not be obvious on examination in the emergency department, and tamponade is frequently misdiagnosed

as congestive heart failure or respiratory disease. Although neoplasm has generally been the most common underlying cause of nonhemorrhagic effusion, [35] [27] some reports [36] [37] have identified infectious complications of the human immunodeficiency virus (HIV) as a common etiology of large nonhemorrhagic pericardial effusion and tamponade (Table 15-2) .

HIV-related effusions have been ascribed to many opportunistic bacterial and viral infections, with mycobacterial infections being the most common. [36] [37] [38] Noninfectious pericardial effusions in HIV have been caused by Kaposi sarcoma and lymphoma. [39] [40]

Cancer is a prominent cause of nonhemorrhagic effusions; the pericardium is involved in 20% of patients with disseminated tumors [41] and 8% of all patients with cancer. [42] There is primary pericardial involvement in 69% of acute leukemias, in 64% of malignant melanomas, and in 24% of lymphomas; however, the incidence of actual tamponade in these malignancies is not known. Of metastases to the pericardium, 35% originate in the lung, 35% in the breast, 15% in lymphomas, and <3% in each of the other cancers. [42] Thus, any patient who is known to have one of these malignancies should be considered at risk for tamponade. Metastasis to the heart is usually a late finding in cancer, and other foci located elsewhere are usually evident. [43] Classic findings of tamponade, such as pulsus paradoxus, are frequently absent in cancer patients with tamponade, and their symptoms are usually attributed to their malignancy. [42]

Radiation pericarditis, particularly after treatment for Hodgkin's disease, is a common cause of effusion. [32] Effusion occurs in approximately 5% of those patients who receive 4000 rad to the heart.

Approximately 15 to 20% of patients on dialysis for renal failure develop pericarditis, and 35% of those with pericarditis develop tamponade. [44] [45] Up to 7% of patients on

chronic dialysis may have effusions, sometimes of 1 L or more. [45] Some series have reported tamponade in 34% of uremic patients who have effusions. [45] Pericardial effusion in renal failure may be managed with dialysis alone in many cases.

Thirty percent of myxedema patients may have pericardial effusions, but few have tamponade. [35] Most of the other

etiologies listed in Table 15-1 are isolated case reports, and their exact incidences have not been determined.

**Other Causes of Pericardial Tamponade**

An interesting but rare cause of cardiac tamponade is pneumopericardium. Pneumopericardium is most commonly seen with pneumothorax and pneumomediastinum as a complication of respiratory therapy in infants, but it may also occur from similar barotrauma in adults. [46] Pneumopericardium also occurs spontaneously in asthma, [47] after blunt chest injury, [48] and even after high-speed motorcycle rides. [49] Pneumopericardium is usually benign, but tension pneumopericardium has been reported as a cause of life-threatening tamponade after blunt chest trauma [50] and after pericardiectomy. [51] The appearance of life-threatening pneumopericardium and tamponade has also been described immediately [52] and 6 days after penetrating chest trauma. [53]

## PATHOPHYSIOLOGY OF TAMPONADE

The pericardium is a tough, leathery sac that encloses the heart. It normally contains about 25 to 35 mL of serous fluid. [54] The pericardium is not rapidly elastic, although it does demonstrate stress relaxation within minutes of increased intrapericardial pressure, providing a slight ability to accommodate sudden increases in fluid. [55] As fluid accumulates, the first 80 to 120 mL is easily accommodated without significantly affecting pericardial pressure (Fig. 15-1) (Figure Not Available) . [56] However, if an

additional 20 to 40 mL is rapidly accumulated, the intrapericardial pressure almost doubles, often leading to sudden decompensation. With chronic effusions

that develop over weeks to months, the pericardium lengthens circumferentially to a huge size and can accommodate liters of fluid.

Pericardial compliance varies considerably in different individuals and various disease states. This compliance helps to determine the pressure-volume response curve (Fig. 15-2) (Figure Not Available) . [54] The pressure-volume relationship demonstrates hysteresis; the withdrawal of a quantity of fluid drops the pressure more than the addition of the fluid raised it.

As pericardial fluid accumulates, the increased intrapericardial pressure is transmitted across the myocardial wall and causes compression of the atria and perhaps the vena cava and pulmonary veins. This reduces right ventricular filling in diastole, producing decreased stroke volume and cardiac output. [57] Pulse pressure narrows as reflex sympathetic stimulation increases. Severe tamponade is produced with intrapericardial pressures of 15 to 20 mm Hg. [58]

Because stroke volume is decreased, heart rate increases to maintain cardiac output. Sympathetic discharge causes both arterial and venous vasoconstriction. [58] [59] Vasoconstriction increases venous pressure, which helps to restore the normal venous-atrial and atrioventricular filling gradients. These compensatory mechanisms are often effective and may permit establishment of a new homeostasis with normal cardiac output.

In chronic effusion and in early tamponade, cardiac contractility is not affected, and myocardial perfusion is normal. [57] [60] [61] As pressure continues to increase, coronary perfusion pressure drops, so in its later stages, tamponade is an ischemic event for the heart. By the time hypotension is measurable, left ventricular blood flow has already decreased 37%. [62] For comparable degrees of hypotension, experimental animals in hemorrhagic shock have five times greater coronary blood flow than animals in cardiac tamponade. [62] Severe

**Figure 15-1** (Figure Not Available) Production of cardiac tamponade by injections of saline into the pericardial sac. Although pericardial space can acutely accommodate 80 to 120 mL of fluid without a significant increase in pericardial pressure, note steep increases in pressure and drop in blood pressure at about 200 mL of saline. Once critical volumes are reached, very small increases cause significant hemodynamic compromise. *(From Fowler NO: Physiology of cardiac tamponade and pulsus paradoxus. II: Physiological, circulatory, and pharmacological responses in cardiac tamponade. Mod Concepts Cardiovasc Dis 47:116, 1978. Reproduced by permission of the American Heart Association, Inc.)*

**Figure 15-2** (Figure Not Available) Relationship of intrapericardial pressure to volume of pericardial fluid. Note that pressure drops more rapidly when fluid is removed than when it accumulates. (From Pories W, Gaudiani V: Cardiac tamponade. Surg Clin North Am 55:573, 1975. Reproduced by permission.)

experimental tamponade is followed by large increases in creatine kinase MB and microscopic evidence of cardiac injury resulting from ischemia. [63]

As intrapericardial pressure continues to rise, the heart's compensatory mechanisms fail. Myocardial ischemia and perhaps lactic acidosis from poor tissue perfusion may be the triggering events that disrupt the uneasy equilibrium. [64] Atrial pressure rises rapidly (Fig. 15-3) (Figure Not Available) . The atria and pulmonary circulation, being at much lower pressure than the systemic arterial pressure, are more vulnerable to the rising intrapericardial pressure. A "pressure plateau" occurs in which right atrial pressure, right ventricular diastolic pressure, pulmonary artery diastolic pressure, and pulmonary capillary wedge pressure are virtually identical.

This equalization of pressures leads to the echocardiographic hallmark of tamponade: right ventricular collapse. At this point hypotension is severe, bradycardia is common, and pulseless electrical activity (PEA) may occur. Unless intrapericardial pressure is immediately decreased, pulmonary blood flow ceases, and cardiac arrest follows. [64]

Total blood volume affects cardiac compensation, and it is possible to encounter a "low-pressure" cardiac tamponade. [65] The hypovolemic patient with tamponade has a decreased venous pressure, which not only decreases cardiac output, but also may obscure the diagnosis, because *distended neck veins or an elevated CVP are not present*. In a patient with a chronic pericardial effusion, the onset of hypovolemia can lower filling pressure enough to precipitate tamponade, and conversely, providing additional volume may temporarily offset increased pericardial pressure.

Ventilation and blood $CO_2$ levels have significant effects on cardiac tamponade. This is of particular significance, because trauma and other patients with tamponade may also have respiratory impairment. Pericardial pressure decreases 3 to 6 mm Hg with a hypocarbia of 24 torr and increases 2 to 4 mm Hg when the $P_{CO_2}$ reaches 57 torr. [66] This degree of hypercarbia-induced pericardial pressure rise can decrease

**Figure 15-3** (Figure Not Available) Summary of physiologic changes in tamponade. RV, right ventricle. (From Shoemaker WC, Carey JS, Yao ST, et al: Hemodynamic monitoring for physiological evaluation, diagnosis, and therapy of acute hemopericardial tamponade from penetrating wounds. J Trauma 13:36, 1973; and Spodick D: Acute cardiac tamponade: Pathologic physiology, diagnosis, and management. Prog Cardiovasc Dis 10:65, 1967. Reproduced by permission.)

cardiac output by 25%. Similarly, fluctuations in intrapleural pressure induced by intermittent positive-pressure ventilation are transmitted to the pericardial space and can reduce cardiac output another 25%. [67] The clinical implications of these findings are that patients suspected of having tamponade should normally be allowed to breathe spontaneously under careful monitoring and should not be ventilated with positive pressure unless it is absolutely necessary, as their hemodynamic status may deteriorate precipitously.

## DIAGNOSIS OF CARDIAC TAMPONADE

### Patient Profile and Symptoms

The clinical diagnosis of pericardial effusion can be difficult. In contrast, pericardial

tamponade is a clinical diagnosis, but specific clinical signs are often inaccurate. Particularly in the setting of acute hemorrhagic tamponade, the time from the first signs of tamponade to full arrest may be brief, and a high level of suspicion to invoke ultrasound or invasive diagnostic testing must be maintained. [68]

Classic clinical findings have been described for tamponade. However, these findings are often clearly present only when the patient is in fulminant tamponade. Ideally, tamponade is diagnosed early, when the patient suffers no more than dyspnea, weakness, or sometimes right heart failure. A common pitfall is to attribute respiratory symptoms (e.g., dyspnea on exertion) to a more common condition such as heart failure or pulmonary pathology and to overlook pericardial effusion until the classic late signs (e.g., hypotension) appear. [69]

Acute pericardial tamponade may resemble tension pneumothorax, acute hemothorax, hypovolemia, pulmonary edema, or pulmonary embolism. Severe right ventricular contusion can mimic the findings of tamponade. [70] The patient is often agitated or panic stricken, confused, uncooperative, restless, cyanotic, diaphoretic, and acutely short of breath. In the late stages, the patient is moribund. Hypotension in the presence of severe cyanosis and distended neck veins is a helpful but late finding.

**Physical Signs**

The classic physical findings of tamponade were first characterized by Beck in 1935. He described two triads, one for acute and one for chronic compression. [71] The chronic compression triad consists of high CVP; ascites; and a small, quiet heart. The triad in acute compression consists of high CVP, decreased arterial pressure, and muffled heart sounds. Unfortunately, in most major trauma series, only about one third of patients demonstrate the complete acute triad, [64] [72] although almost 90% have one or more signs. [6] *The simultaneous occurrence of all three physical signs is a very late manifestation of tamponade and is usually seen only shortly before cardiac arrest* (see Fig. 15-3) (Figure Not Available) .

Careful hemodynamic monitoring reveals much earlier changes that indicate the progression of tamponade (Table 15-3) (Table Not Available) . [73] In grade I tamponade, cardiac output and arterial pressure are normal, but CVP and heart rate are increased. In grade II tamponade, blood pressure is normal or slightly decreased, CVP is increased, and tachycardia persists. In grade III tamponade, the classic findings of Beck's acute triad occur. Although this sequence represents the natural history of acute tamponade, the time course varies. Some patients are stable at a given stage for hours; others proceed to cardiac arrest within minutes. [64] [73] Unfortunately, not all patients with early tamponade respond with a predictable pattern of change in vital signs. Brown and coworkers found that 6 of 18 patients with tamponade, defined through right heart catheterization, responded to tamponade with elevated systolic blood pressure. [74] After pericardiocentesis, these patients had a marked reduction in systolic blood pressure accompanied by increased cardiac output. All of these patients had previously been hypertensive.

The measurement of pulsus paradoxus is a procedure in its own right (see Chapter 70) . Pulsus paradoxus is defined as an exaggeration of the normal inspiratory fall in blood pressure. [59] [72] A paradoxical pulse (pressure) is one of the classic physical signs of tamponade, but it is not pathognomonic. It is also caused by pulmonary emphysema, asthma, labored respirations, obesity, cardiac failure, constrictive pericarditis, pulmonary embolism, and cardiogenic shock. [6] [33] [64] Measuring the paradoxical pulse is difficult and time consuming, and any frightened, hypotensive patient with labored breathing can demonstrate this finding (Fig. 15-4) .

If the difference between inspiratory and expiratory systolic blood pressures is >12 mm Hg, the paradoxical pulse is abnormally high. [75] Most patients with proven tamponade will demonstrate a difference of 20 to 30 mm Hg or more during the respiratory cycle. [6] [33] [64] This may not be true of patients with very narrow pulse pressures (typical of grade III tamponade); they will have a "deceptively small" paradoxical pulse of 5 to 15 mm Hg. The decrease in magnitude of pulsus paradoxus with hypotension occurs because the paradoxical pulse is a function of actual pulse pressure, and the inspiratory systolic pressure may be below the level at which

---

**TABLE 15-3** -- Shoemaker System of Grading Cardiac Tamponade
*From Shoemaker WC, Carey SJ, Yao ST, et al: Hemodynamic monitoring for physiologic evaluation, diagnosis, and therapy of acute hemopericardial tamponade from penetrating wounds. J Trauma 13:36, 1973.*

(Not Available)

---

diastolic sounds disappear. [59] For this reason, the ratio of paradoxical pulse to pulse pressure is a more reliable measure. A paradoxical pulse >50% of the pulse pressure is abnormal. [59]

Pulsus paradoxus has been correlated with the amount of impairment of cardiac output by tamponade. In atraumatic patients, a 15% pulsus paradoxus in the face of relative hypotension was found in 97% of patients with moderate or severe tamponade and only 6% of patients with absent or mild tamponade. [75] A similar study of right ventricular diastolic collapse by echocardiography found that an abnormal pulsus paradoxus had a sensitivity of 79%, a specificity of 40%, a positive predictive value of 81%, and a negative predictive value of 40%. [76]

The absence of a paradoxical pulse does not rule out tamponade. Although the mean paradoxical pulse was 49 mm Hg in one series of nonhemorrhagic tamponade, [35] 23% of the patients had a paradoxical pulse of <20 mm Hg, and 1 patient had no measurable paradoxical pulse. An abnormal pulsus paradoxus has been reported to be absent in tamponade when there is an atrial septal defect, aortic insufficiency, localized collections of pericardial blood, or extreme tamponade with hypotension. [65] It may also be absent when left ventricular diastolic pressure is intrinsically elevated owing to poor left ventricular compliance. This was seen in one

**Figure 15-4** Normally systolic blood pressure drops slightly during inspiration. To measure pulsus paradoxus, the patient breathes normally while lying at a 45° angle. The blood pressure cuff is inflated well above systolic pressure and slowly deflated. When the pulse is first heard only during expiration, this is the upper value. The cuff is deflated until the pulse is heard during both inspiration and expiration, and this is the lower value. The difference in the two values is the amount of pulsus paradoxus. A difference of more than 12 mm Hg is abnormal.

half of uremic patients with tamponade. [45] [77] In traumatic tamponade, pulsus paradoxus is deemed unreliable. [6] [77] [78] [79] In one study, only 35% of trauma patients had an abnormal paradoxical pulse when elevated CVP and decreased heart sounds were present. [79] In another study of 197 traumatic cases, only 8.6% of the diagnoses of tamponade were made by finding an abnormal pulsus paradoxus. [80]

Although the absence of a paradoxical pulse rules against severe tamponade, it does not completely rule it out. Whether time is taken to determine pulsus paradoxus depends on the patient's status. If the patient is moribund or rapidly deteriorating, taking time to check this parameter is obviously a poor choice of priorities.

**Venous Distention**

Venous distention, reflecting increased CVP, is also a late sign in cardiac tamponade (see Fig. 15-3) (Figure Not Available) . It may be masked by venoconstriction as a result of vasopressors (e.g., dopamine), intrinsic sympathetic discharge, or hypovolemia. [33] [64] [73] [78] Neck vein distention may be obvious clinically, but the measured CVP is more reliable than the presence of venous distention. The CVP reading should take into account positive-pressure ventilation and the effects of a Valsalva maneuver. Most patients with significant tamponade will have a CVP of 12 to 14 cm $H_2$ O. [78] *Hypovolemia changes the intrapericardial pressure-volume curve in tamponade and will lower the CVP reading at any given stage in the tamponade process.*

Animal studies have documented that right atrial pressure can be normal in tamponade when hypovolemia is present. One case of low-pressure cardiac tamponade was reported in a patient with no jugular venous distention, no paradoxical pulse, and a right atrial pressure of 8 mm Hg. [65] Thus although the initial CVP reading is useful and diagnostic if grossly elevated (e.g., 20 to 30 cm $H_2$ O), [51] [78] a series of CVP readings looking for an upward trend is the most sensitive diagnostic tool. [78] A rising CVP, especially when there is persistent hypotension, is extremely suggestive of tamponade in the trauma patient. In the rare case of the hypovolemic patient in whom tamponade is

suspected but who demonstrates a low CVP, a fluid challenge will help clarify the situation and will also improve cardiac output at least temporarily. [65]

**Ancillary Testing**

Routine chest radiographs and ECGs may be useful in increasing the level of suspicion for pericardial effusion and

tamponade. Noninvasive diagnosis of effusion, however, must be made by computed tomography or, preferably, cardiac ultrasound.

### Chest Radiographs

Chest radiographs are not useful in the diagnosis of acute traumatic tamponade, because *the cardiac size and shape do not change acutely.* However, the radiographs may reveal hemothorax, bullet location, or even pneumopericardium.

In the nontrauma patient with chronic effusion, a chest film often reveals an enlarged, sac-like "water bottle" cardiac shadow. Unfortunately, it is difficult to differentiate pericardial from myocardial enlargement, and radiographs cannot be used to distinguish between simple pericardial effusion and tamponade. One finding that is useful in identifying effusion on the plain chest film is the epicardial fat pad sign. The water density space between the radiolucent epicardial fat and the mediastinal fat represents the pericardial tissues and is normally <2 mm. An increase in this width suggests pericardial fluid or thickening (Fig. 15-5) . This sign may be seen in 41% of upright lateral and 23% of frontal chest films in proven pericardial effusion. [81] The diagnostic value may be enhanced by using a supine rather than upright cross-table, lateral chest radiograph. Obtaining a supine lateral film increases the sensitivity of the epicardial fat pad sign from 31 to 51%. [82]

### Electrocardiograms

ECGs may suggest, but should *not* be used to diagnose, pericardial effusion or cardiac tamponade. Most ECG changes, such as PR-segment depression, low-voltage QRS complexes, and electrical alternans, have acceptable specificity but poor sensitivity for pericardial effusion or tamponade. [33] [38] Low voltage is defined as a QRS amplitude 5 mV in all limb leads (or a sum of the limb lead QRS amplitude 30 mV), and PR depression is defined as 1 mV in at least 1 lead other than aVR. In 1 study correlating the ECG with echocardiographic evaluation, ECG signs had an overall sensitivity of only 1 to 17% and a specificity of 89 to 100% for pericardial effusion. [33] Others have demonstrated significantly higher sensitivity, i.e., in the range of 32 to 68% for voltage criteria. [84] PR-segment depression is the most common ECG finding in pericardial tamponade, and low voltage is most commonly associated with a moderate to large effusion. It is important to note that none of the ECG findings differentiate tamponade from effusion.

Electrical alternans is caused by pendular motion of the heart within the pericardial sac.

[85] Alternans of the QRS complex has been seen in about 22% of medical tamponade cases [69] but in only 5% of cancer patients with tamponade. [42] Electrical alternans of both the P wave and the QRS complex (total electrical alternans) is a rare finding but when seen is thought to be pathognomonic of tamponade (Fig. 15-6) (Figure Not Available) . [33] [86] Alternans does not always appear in the standard ECG leads; a bipolar chest lead (Lewis lead) may be needed to detect it.

**Echocardiography**

Echocardiography is the best available tool for diagnosing pericardial effusion and has the further advantage of being noninvasive. [87] Echocardiography is very sensitive in the diagnosis of pericardial effusion and tamponade. [88] [89]

The disadvantages of echocardiography are that it requires ultrasound equipment and is dependent on a skilled operator who is specifically trained in echocardiography. Even when immediately available, echocardiography may take at least 5 minutes, which may be too much time for a patient who is deteriorating rapidly.

**Figure 15-5** Epicardial fat pad sign. The water density space between the radiolucent epicardial fat and the mediastinal fat represents the pericardium and its contents and should be 2 mm or less. An increase suggests pericardial fluid or thickening. *A,* Left anterior-oblique chest film. *B,* Lateral chest film. On acute tamponade, the chest radiograph has very minimal diagnostic value.

**Figure 15-6** (Figure Not Available) Overall, the ECG has a low sensitivity for pericardial effusion or tamponade, but PR depression, low voltage, or electrical alternans may be seen. Lewis lead electrocardiogram (ECG) showing total electrical alternans of both amplitude and configuration of P and QRS complexes. This is rarely seen but is almost pathognomonic of tamponade. Note that electrical alternans may not be evident in standard ECG leads. (From Sotolongo RP, Horton JD: Total electrical alternans in pericardial tamponade. Am Heart J 101:854, 1981. Reproduced by permission.)

The diagnosis of effusion is easily made by visualizing a large area of fluid, often best seen behind the heart. This view will also demonstrate the ventricular wall and quickly distinguishes the patient with a large effusion from the patient with congestive heart failure and a dilated ventricle. False-positive results may be obtained if a large amount of subepicardial fat is present. [90]

Effusion is not synonymous with tamponade, and the volume of fluid needed to produce tamponade in an individual depends on the thickness of the ventricular myocardium, the rate of fluid accumulation, and the distensibility of the pericardium. Echocardiographic diagnosis of tamponade is best made on the observation of right ventricular diastolic collapse. [91] [92] Other useful echocardiographic suggestions of tamponade are observation of the heart swinging rhythmically in the pericardial effusion, excessive respiratory variation in the size of the ventricles, greatly decreased right ventricular size, and pseudoprolapse of the mitral valve. [77]

Although right ventricular or atrial collapse has been touted to be highly specific and sensitive for tamponade, [76] when the definition of tamponade is based on clinical

criteria, the picture becomes less clear. Whereas echocardiography is very sensitive for tamponade, it may be nonspecific. [89] [93] [94] For example, in a group of 50 patients with an echocardiograph diagnostic for tamponade, 94% had a systolic blood pressure 100 mm Hg and 58% had a cardiac index 2.3 L/min/m [2] . [89] It is unclear whether the subset of patients with electrocardiographically "proven" tamponade but no clinical signs of tamponade have a natural history that differs from those with a large, nontamponade pericardial effusion. One author has suggested, "In some of these patients, when the etiology is known and the disease can be treated effectively with medication . . . pericardial drainage may not be necessary." [94]

If echocardiographic determination of tamponade is overly sensitive, do the echocardiographic signs associated with tamponade provide predictive value regarding outcome? In a retrospective evaluation of 187 hospitalized patients with pericardial effusion, the effusion size alone was found to have a strong predictive value for patient outcome when measured in terms of eventual tamponade or the combined end point of tamponade, surgical drainage, or pericardiocentesis. [95] The addition of criteria for tamponade, right atrial and ventricular collapse, and inferior vena cava (IVC) plethora added little, if any, prognostic value. Wall and coworkers, in an analysis of 57 patients with new, large pericardial effusions, found that these additional findings did not differentiate patients with and without tamponade, although cardiac tamponade occurred in almost 50% of patients, regardless of these findings. [96]

The risk of performing pericardiocentesis without echocardiographic determination of pericardial fluid was demonstrated by the Krikorian series. [27] Of patients with a clinical picture of tamponade, 17% actually had constrictive pericarditis, 16% had congestive heart failure and fluid overload, and 5% had obstruction of the superior vena cava. None of these patients could be expected to benefit from pericardiocentesis, and all were at risk for complications.

**Computed Tomography**

Although in most circumstances computed tomography (CT) is less readily available than echocardiography and requires that the patient be transported to the site of the CT equipment, CT is effective in defining the presence and extent of pericardial effusion in the stable patient. [97] In certain circumstances, CT can provide a more definitive diagnosis than echocardiography. In one series, eight equivocal echocardiograms were evaluated by CT. [98] Two patients thought to have pericardial effusion by ultrasound were found by CT to have pleural effusions. Another patient with pericardial effusion by ultrasound was found by CT to have an epicardial lipoma. Three loculated pleural effusions not seen by ultrasound were defined by CT. A final 2 patients had hemopericardium visualized by CT but not ultrasound. In circumstances where the patient is stable and ultrasound produces equivocal results or is not available, CT may provide a definitive diagnosis of pericardial effusion.

## INDICATIONS FOR PERICARDIOCENTESIS

There are two indications for pericardiocentesis: (1) to diagnose the cause or presence of a pericardial effusion and (2) to relieve tamponade. The former is an elective

procedure and ideally should be accomplished under ultrasound guidance. The latter may be semi-elective and performed with ultrasound guidance or emergent and performed blind with ECG assistance.

**Diagnostic Pericardiocentesis**

The use of pericardiocentesis for diagnosis of the etiology of nonhemorrhagic effusions is widespread, although opinions of its utility vary. [32] [99] [100] Neoplastic cells, blood, bacteria, viruses, and chyle can be sought. Measurement of pericardial fluid pH can be helpful, because inflammatory fluid is significantly more acidotic than noninflammatory fluid. [101] When a specific etiology is suspected, additional diagnostic testing may be useful (e.g., adenosine deaminase in tuberculosis, and carcinoembryonic antigen in suspected malignancy). [102]

The diagnostic accuracy of pericardiocentesis varies greatly from series to series, depending on the vigor with which a definitive etiology was sought and the prevalence of certain etiologies in the patient population under consideration. In one large series, fluid was obtained in 90% of the taps, but a specific etiologic diagnosis was obtained in only 24% of the fluid specimens. [27] Certain diagnoses are unlikely to be made from pericardial fluid. Pericardial fluid has been shown to give false-negative cytologic results in several cases of lymphoma and mesothelioma. [27] In HIV patients, effusions caused by Kaposi sarcoma and cytomegalovirus have been diagnosed by pericardial biopsy after fluid studies were nondiagnostic. [103] [104]

An alternative diagnostic tool is subxiphoid pericardiotomy. This technique, performed in the operating suite, obtains both fluid and a pericardial biopsy specimen. It is more likely to provide a definite diagnosis and has been performed safely without general anesthesia. [105] [106] In a prospective series of 57 patients, 36% obtained a definitive diagnosis; 40%, a probable diagnosis; 16%, a possible diagnosis; and 7% remained undiagnosed with subxiphoid pericardiotomy. [107] Although it is uncertain whether this technique is safer than ultrasound-guided pericardiocentesis, published reports show a low rate of complications. [107]

Regardless of technique, the need to sample small effusions or obtain pericardial tissue has been questioned. A prospective series found a diagnostic rate of 6% with pericardial fluid and 5% with pericardial tissue when a small persistent effusion was sampled for the specific purpose of diagnosis. In contrast, when patients from the same population had therapeutic intervention for tamponade, the yields from fluid and tissue were 54% and 22%, respectively. [100]

The use of pericardiocentesis as a diagnostic tool in traumatic tamponade is limited. When used diagnostically to determine the presence of pericardial bleeding in trauma, the procedure has a false-negative rate of between 20% and 40%. [78] [108] [109] [110] The reason for the high false-negative rate (defined as no blood aspirated) is well demonstrated by typical stab wounds of the heart. [8] [111] Ninety-six percent of the patients had blood in the pericardium, but it was clotted in 41% of the patients and partially clotted in another 24%. In only 19% was the blood completely fluid and thus

capable of giving a true-positive result on pericardiocentesis.

**Therapeutic Pericardiocentesis**

### Tamponade of Uncertain Etiology

The most common reason for performing pericardiocentesis in the emergency department (ED) is as part of the treatment for cardiac arrest or in peri-arrest situations. In particular, the presentation of pulseless electrical activity (PEA) with elevated jugular venous pressure should cause immediate consideration of pericardiocentesis. In this setting, blind, ECG-guided pericardiocentesis can be life-saving. However, the overwhelming majority of patients with PEA have neither significant effusion nor tamponade, and other etiologies for the PEA also should be sought. Pericardiocentesis also may be considered in other presentations of effusion with existing or incipient tamponade.

### Tamponade Caused by Nonhemorrhagic Effusions

Pericardiocentesis is often, at least temporarily, therapeutic in cardiac tamponade. Most nonhemorrhagic effusions are liquids that can be drained easily through a small needle. Removal of even a small amount of fluid can immediately and dramatically improve blood pressure and cardiac output. Pericardiocentesis relieves tamponade due to nonhemorrhagic effusions in 60 to 90% of cases. [35] [27] [42] Patients in whom it fails often have purulent pericarditis or malignant invasion of the pericardium.

Pericardiocentesis without catheter placement may be much less useful for long-term management of these patients; 26% of the patients in the study by Guberman and coworkers eventually required pericardial resection. [35] In Krikorian's series, 24% of the patients were managed successfully with one pericardiocentesis, 37% needed multiple taps or an indwelling catheter, and 39% required surgical drainage. [27] Fifty-five percent of the last group had traumatic hemopericardium.

Patients with renal failure and pericardial effusion may be better managed by dialysis than pericardiocentesis. In one series, 63% of these patients were successfully managed with dialysis alone, and only 6% needed surgical treatment over the long term. [27] Tamponade is less frequent with pericarditis when it occurs within the first months of dialysis, and such patients are much more likely to be successfully managed without invasive intervention. [44] When invasive treatment is needed for dialysis patients, pericardiocentesis is probably a poor choice; 9 of 10 patients who received it had complications in one series, and it was the only invasive treatment that resulted in death. [44]

An algorithm for the urgent management of nonhemorrhagic cardiac tamponade is shown in Figure 15-7 .

### Use in Hemorrhagic Tamponade

*Pericardiocentesis is never the definitive treatment in hemorrhagic tamponade.* [112] [113] Although aspiration of a small quantity of fluid may cause dramatic improvement, blood usually reaccumulates. [33] [86] Thus, patients with pericardial hemorrhage ultimately require thoracotomy to explore and repair the cardiac injury.

One of the greatest potential drawbacks of pericardiocentesis in traumatic tamponade is that it may delay thoracotomy. In one study of 25 trauma patients with cardiac injury, [112] all of those who were operated on within 2 hours of injury survived, regardless of age or type of wound. With greater delay, none survived. Sugg and colleagues, in a study of 459 similar patients, found a mortality rate of 43% when pericardiocentesis was the sole treatment, but only 16% when surgery was performed. [109] Most investigators agree that with early thoracotomy and little or no reliance on pericardiocentesis, the number of deaths due to stab wounds has decreased. [78] [110] [113] [114] Sugg and associates reported that 10 of 18 patients with traumatic tamponade who were managed by repeated pericardiocentesis alone died within 1 to 2 hours. [109] At autopsy, all patients had completely repairable wounds.

Nonetheless, while other temporizing treatments are instituted (see discussion below) and arrangements for definitive surgical treatment are being made, pericardiocentesis may temporarily improve the patient's hemodynamic situation (Fig. 15-8) . Some clinical evidence supports the usefulness of pericardiocentesis as a temporizing measure. In a study of 174 patients with tamponade from penetrating trauma, 96 underwent operating room thoracotomy, 44 underwent emergency department thoracotomy, and 34 received

**Figure 15-7** Management of *nontraumatic* cardiac tamponade. IV, intravenous line; CVP, central venous pressure; ECG, electrocardiogram.

only pericardiocentesis followed by observation. [80] Of those who underwent operating room thoracotomy, 68% were hemodynamically unstable, and preoperative pericardiocentesis decreased the mortality rate from 25 to 11%. Ninety-one percent of those who underwent emergency department thoracotomy were unstable, and pre-thoracotomy pericardiocentesis decreased the mortality rate from 94 to 63%. For the unconscious and hypotensive or agonal patient,

**Figure 15-8** Management of *traumatic* cardiac tamponade. IV, intravenous lines; CVP, central venous pressure; ECG, electrocardiogram; R/O, rule out.

emergency thoracotomy is the preferred treatment (see Chapter 17) .

When a trauma patient's condition is relatively stable, but a high level of suspicion for a penetrating cardiac wound is present, an alternative to thoracotomy is the subxiphoid pericardial window. [105] [115] [116] The procedure has been done under local anesthesia, and although it is possible to perform the procedure in the ED, [116] most authors believe the procedure should be reserved for the operating suite. [117] [118] [119]

## CONTRAINDICATIONS

There is no absolute contraindication to pericardiocentesis. It should not be performed when better treatment modalities are immediately available (e.g., dialysis for uremic patients and immediate surgery for trauma patients). For diagnostic or nonemergency pericardiocentesis, the absence of echocardiographic or CT diagnosis is a relative contraindication, because the complication rate increases dramatically under such circumstances. If ultrasound or fluoroscopic guidance is available, it should be used in nonemergent situations.

## EQUIPMENT FOR PERICARDIOCENTESIS

### Fluoroscopic or Ultrasound Guidance

Pericardiocentesis is ideally performed in the cardiac catheter laboratory under fluoroscopic guidance. In the emergency department, as well as elsewhere in the hospital, echocardiography is useful for directing pericardiocentesis. With ultrasound, the area of the heart with the greatest fluid accumulation can be accurately identified and its relationship to the body wall clarified. [120] [121] An entry site and angle of penetration can then be chosen that have the greatest likelihood of obtaining fluid while simultaneously avoiding vital structures. Ultrasound also can be used to identify when the needle tip enters the pericardial space, although visualizing the needle with ultrasound can be difficult. [122] Specially made guides are available to allow visualization of the needle during the procedure and reduce complications. [123] Without

**Figure 15-9** Equipment for emergent pericardiocentesis: long, 18-ga spinal needle; wire with alligator clips for connection to the electrocardiograph machine; and syringe (three-way stopcock optional). Sterile skin preparation and local anesthetic are also required.

**Figure 15-10** An example of the contents of a prepackaged pericardiocentesis set: finder needle, Seldinger wire, dilator, catheter guide, and pigtail catheter. Sterile skin preparation and local anesthetic are also required.

ultrasound or fluoroscopy, pericardiocentesis is blind, and vital structures are vulnerable to injury. These techniques are beyond the scope of this text, and the clinician should enlist the assistance of a skilled imager when using them.

### Electrocardiographic Assistance

Although the procedure can be performed with only a syringe and a spinal needle, ECG monitoring is desirable. An alligator clamp is used to connect the needle to *any* of the precordial leads (V leads) of a properly grounded ECG device (Fig. 15-9) . Generally the V lead (usually $V_1$ or $V_5$ ), which permits a continuous display during rhythm monitoring,

is used.

**Other Equipment**

The traditional needle choice has been a 7.5- to 12.5-cm (3- to 5-inch), 18-ga spinal needle with an obturator. It is best to leave the obturator in the needle during initial passage through the skin to avoid obstruction of the needle lumen. More recently, the shorter Teflon-sheathed Intracath needle has been used. Alternatively, the clinician can use the guide wire (Seldinger) technique, inserting a plastic catheter over a flexible guide or J wire. With this technique, an 18-ga, thin-walled needle is used for placement of the wire. The catheter (after removal of the accompanying introducer) may be left in place for prolonged drainage, if needed. [124] [125]

For drainage of blood, pus, or other viscous effusions, a large catheter such as a No. 7 to 9 Fr Cordis sheath should be inserted. [126] Alternatively, the guide wire technique can be used to insert a radiopaque, 16-ga, flexible, fenestrated, central venous catheter, which can then be connected to closed suction drainage and left in place for long periods of time. [127] Pigtail catheters with side and end holes or nephrostomy drainage catheters also can be used. [125] Multilumen catheter patency can be maintained by slow continuous flush with heparinized saline solution. [125] Complete "sets" containing necessary equipment for placing a catheter using the guide wire technique are commercially available (Fig. 15-10) , including sets designed for pediatric use. [128]

A three-way stopcock may be attached to the needle or catheter to allow removal of more than one filled syringe without much movement of the needle. The continuous motion of the heart may require minor changes in needle or catheter position during the procedure. Lengthy or repeat drainage is much safer if the steel needle is withdrawn and a plastic catheter is left in place.

## PROCEDURE

**Temporizing Measures**

While preparing for pericardiocentesis in the unstable patient or attempting to stabilize the patient while the operating suite is readied for thoracotomy or subxiphoid pericardiotomy, temporizing measures should be considered. In the patient with suspected tamponade and without jugular venous distention, the administration of a fluid bolus may improve hemodynamics. [65] In the setting of nonpenetrating tamponade, a fluid challenge has been recommended [56] [129] ; animal experiments have found this to be beneficial, with or without nitroprusside for afterload reduction. [130] However, a follow-up prospective evaluation in patients with tamponade found no benefit from either fluid challenge or nitroprusside; cardiac output remained unchanged at a mean of 5.1 L/min, in contrast to 9.1 L/min after pericardiocentesis. [131] In the trauma patient with penetrating cardiac injury, fluid resuscitation may produce improvement or deterioration. Animal experiments indicate that the response depends on whether fluid infusion produces recurrent bleeding from the cardiac wound. [132] One report found that dextran solution for volume expansion produced significant hemodynamic improvement in patients with subacute ventricular free wall rupture after acute myocardial infarction. [30]

In summary, judicious volume expansion may produce temporary beneficial hemodynamic results, but this is not uniformly true.

Pressors also have been recommended as a temporizing measure in tamponade. Dopamine, dobutamine, norepinephrine, and isoproterenol have been evaluated. Norepinephrine produced increased cardiac output in animal models of tamponade [133] [134] but failed to increase cardiac output in patients with malignant effusion. [133] Isoproterenol produced increased cardiac output in animal models but detrimentally affected cardiac blood flow. [133] Both dopamine and dobutamine have produced increased cardiac output and other improvements in hemodynamics in the setting of tamponade. [20] [134] Either of these agents may be helpful as a temporizing agent in tamponade, but dobutamine may be preferable on theoretical grounds because of its greater beta activity. [134]

**Preparation**

All necessary equipment must be checked and laid out in advance. Full resuscitation equipment must be on hand, including a defibrillator. The patient must have an IV line in place and be attached to a cardiac monitor. The nonemergency patient may require sedation, but in an emergency, pericardiocentesis is usually performed on patients who are already obtunded or unresponsive as a result of low cardiac output. Use of sedation in these patients not only is unnecessary, but also carries a high risk of hemodynamic or respiratory deterioration. Premedication of the patient with atropine may help to prevent vasovagal reactions. When possible, the presence of pericardial effusion and the optimal anatomic approach should be determined in advance by echocardiography. If surgery may be needed, preparations should already be under way to ensure prompt availability of both an operating room and a surgeon.

If the patient's clinical condition permits, the chest should be elevated at a 45° angle to bring the heart closer to the anterior chest wall. If the abdomen is distended because of gastric contents or previous positive-pressure ventilation, a nasogastric tube should be used to decompress the stomach. The entire lower xiphoid and epigastric area should be carefully prepared with 10% povidone-iodine solution and sterilely draped, if time permits.

If the patient is awake, the skin and the proposed route of the pericardial needle should be anesthetized by infiltration with 1% plain lidocaine or 0.5% bupivacaine. Note that the pericardium is very sensitive and should be anesthetized in patients who are awake. [124]

**Anatomic Approach**

The choice of anatomic approach in the past has been governed largely by conjecture and theory, not by actual study of patients with pericardial effusion. Traditionally the subxiphoid approach was preferred and is widely touted in most texts and articles as by far the optimal choice. However, two-dimensional echocardiography allows direct visualization in the individual patient of both the areas of maximal effusion and the location of vital structures, and studies of echocardiography-directed pericardiocentesis have found that the intercostal space near the heart apex is usually the best site for

puncture, not the traditional subxiphoid approach. [121] [126] Careful cadaver studies have corroborated this finding, demonstrating greater safety with a parasternal approach in the fifth intercostal space and showing that the greatest number of injuries (usually to the right atrium) occurred with any variant of the subxiphoid approach. [13] In contrast, studies of intracardiac injection using the same routes have found an increased incidence of pneumothorax when parasternal or intracostal approaches are used (see discussion of complications of pericardiocentesis). This risk may increase with underlying lung disease. Whenever time and the patient's condition permit, clinicians should rely on echocardiography to define the extent of and optimal approach to pericardial effusion. When time or circumstances prevent the use of ultrasound, the clinician should use the approach with which he or she is most familiar.

**Parasternal Approach**

In this approach, the needle is inserted perpendicular to the skin in the left fifth intercostal space medial to the border of cardiac dullness (Fig. 15-11) . Older texts identify the puncture site as being at least 3 to 4 cm lateral to the sternal border to avoid the internal mammary artery. However, anatomic studies indicate that penetration immediately lateral to the sternum is less likely to cause this complication. [13]

**Subxiphoid Approach**

In the traditional subxiphoid approach, the needle is inserted between the xiphoid process and the left costal margin at a 30° to 45° angle to the skin (Fig. 15-12) . Because the heart

**Figure 15-11** Parasternal approach for pericardiocentesis. The patient is depicted in a supine position, although a preferable position would be sitting at a 45° angle, if the patient's clinical condition permits.

is an anterior structure, an angle >45° may intercept the liver or stomach. In this approach, the needle enters the pericardium at the angle at which it becomes the diaphragmatic pericardium. Recommendations as to where to aim the needle vary from the right shoulder to the left shoulder and all points in between, including the sternal notch. [124] [129] The only anatomic study that has been done demonstrated that in fact, the subxiphoid approach is likely to injure the thin-walled

**Figure 15-12** *A* and *B*, Xiphosternal approach for pericardiocentesis. The needle is aimed for the sternal notch or the left shoulder. Note the electrocardiography monitor. Although the patient is shown in a supine position, a preferable position would be sitting at a 45° angle, if the patient's condition permits. This general approach is also used for intracardiac injection of advanced cardiac life support drugs.

right atrium when one aims for the right shoulder. [13] Aiming for the left shoulder directs the needle toward either the left ventricle or the anterior wall of the right ventricle (Fig. 15-13) (Figure Not Available) .

**Apical Approach**

In the less commonly used apical approach, the needle is inserted 1 cm outside the apex beat in the intercostal space below the apex beat and within the area of cardiac dullness, and aimed toward the right shoulder. [124] If the apex cannot be palpated, the needle is inserted just inside the area of cardiac dullness. This area is close to the lingula and left pleural space, and pneumothorax is more frequent; a concomitant pleural effusion may be inadvertently tapped. In theory, this technique is used because the coronary vessels are small at the apex, and if a ventricle is entered, it is the thick-walled left ventricle, which is more likely to seal off any ventricular injury. Data are insufficient to say whether these theoretical advantages are important.

**ECG Monitoring**

After the skin has been punctured but before the pericardial needle is advanced, any obturator in the needle is removed, and an aspirating syringe is attached. At this time, ECG monitoring is begun by attaching a sterile cord with alligator clips (see Fig. 15-9) from the pericardial needle to any precordial lead (V lead) of the ECG machine. The V lead is then recorded, as the needle becomes an "exploring electrode." The machine must be properly tested and internally grounded. Small current leaks can induce dysrhythmias. [33] The purpose of the ECG monitoring is to prevent ventricular puncture. When the needle touches the epicardium, a current-of-injury pattern is noted on the ECG (Fig. 15-14) . This current of injury may be local and could be missed if a lead other than a V lead is monitored or if a cardiac monitor (which has a lower frequency response than the ECG machine) is used. Usually one notes ST-segment elevation on contact with the heart or pericardium in the absence of an effusion, but a premature contraction or other ventricular dysrhythmia also may be induced by direct mechanical stimulation of the ventricular epicardium by the needle. Contact with the atrium can cause atrial dysrhythmias, marked elevation of the PR segment, or atrioventricular dissociation. [15] If there is abnormal myocardial scarring secondary to infarction or other diseases or if there is malignant infiltration of myocardium, no current of injury may be generated. [16] Thus, ECG monitoring is not infallible in preventing myocardial penetration. In addition, the incessant motion of the heart makes it almost impossible to merely *touch* the epicardium.

With constant ECG monitoring, the operator slowly advances the needle and syringe while gently aspirating with the syringe. The needle will penetrate the pericardium (a barrier whose penetration usually cannot be palpated) at about 6 to 8 cm below the skin in adults and 5 cm or less below the skin in children. [54] The patient who is awake may complain of sharp chest pain as the sensitive pericardium is entered. When pericardial content is aspirated, the needle should not be advanced further. If a current of injury is noted (see Fig. 15-14) , the needle is touching epicardium and can easily lacerate myocardium or coronary vessels. The needle should be withdrawn a few millimeters until the

**Figure 15-13** (Figure Not Available) During "blind" pericardiocentesis, the subxiphoid approach is recommended. A short needle (16- or 18-ga) is inserted into the left xiphocostal angle perpendicular to

the skin and 3 to 4 mm below the left costal margin *(A)*. After advancing the needle to the inner aspect of the rib cage, the needle's hub is depressed so that the needle points toward the patient's left shoulder. The needle is then cautiously advanced about 5 to 10 mm until fluid is reached *(B)*. The fingers may sense a distinct "give" when the needle penetrates the parietal pericardium. Successful removal of fluid confirms the needle's position. The syringe is then disconnected from the needle, and the flexible tip of the guide wire is advanced into the pericardial space under fluoroscopic guidance *(C)*. The needle is withdrawn and replaced with a soft, multihole pigtail catheter (No. 6 to 8 Fr) using the Seldinger technique. After dilating the needle tract, the catheter is advanced over the guide wire into the pericardial space *(D)*. Once the catheter is properly positioned, aspiration of fluid should result in rapid improvement in blood pressure and cardiac output, a decrease in atrial and pericardial pressures, and a decrease in the degree of any paradoxical pulse *(E)*. Electrical alternans, if present, also decreases or disappears. (From Spodick DH: The technique of pericardiocentesis. J Crit Illness 2:91-96, 1987.)

**Figure 15-14** Current of injury. There is an obvious change in the electrocardiogram when the pericardiocentesis needle touches the epicardium. Following slight withdrawal *(arrow)*, the ST-segment elevation diminishes.

current of injury disappears. At this point, the needle should be safely positioned in the pericardial space, although heart motion may quickly bring it back into contact with the myocardium. This is particularly a risk if the presence of a large effusion has not been demonstrated by ultrasound.

**Fluid Aspiration and Evaluation**

An attempt is then made to drain pericardial fluid or blood. If blood is obtained, the possibility of cardiac puncture should be entertained. If fluoroscopy is available, the injection of a small amount of contrast will quickly disclose intracardiac placement. In other circumstances, the needle may need to be repositioned and the aspirate reexamined. Laboratory tests may help distinguish circulatory blood from hemorrhagic pericardial fluid. The latter should have a lower hematocrit measurement than venous blood. Substantially different hematocrit values rule out the possibility that the needle was in a cardiac chamber. Hemorrhagic pericardial fluid usually is about 0.10 pH unit more acid than simultaneously obtained arterial blood. [101] Bloody pericardial fluid may clot, particularly in traumatic situations in which bleeding is brisk, so clotting of the aspirated blood does not eliminate the possibility of a pericardial source. Nonclotting blood is indicative of defibrinated pericardial blood. Practically, however, there is rarely time for such analysis.

If an indwelling catheter is to be placed, a guide wire should be advanced through the needle (see Fig. 15-13) (Figure Not Available) . A dilator is passed over the needle to expand the needle tract. The guide wire should be maintained in sight and stabilized at all times. If intracardiac placement of the needle or guide wire is suspected, positioning must be verified by ultrasound or fluoroscopy or by using the techniques described above *before* the needle tract is dilated. Once the tract has been dilated, the pigtail catheter is placed over the guide wire. If the dilator is not used, particularly with the subxiphoid approach, the pigtail catheter tip may hang in the subcutaneous (SQ) tissue, making placement difficult.

After the catheter is placed, or if a decision is made to do a single aspiration, as much

fluid as possible should be aspirated from the pericardium. The removal of even 30 to 50 mL may result in marked clinical improvement in patients with tamponade. The catheter may be placed for continuous or intermittent drainage. A chest film should be obtained after the procedure to rule out iatrogenic pneumothorax. Patients should be monitored closely for 24 hours for signs of reaccumulating fluid or iatrogenic complications from the procedure. Repeat ultrasound examination is wise. Diagnostic evaluation of nonhemorrhagic fluid is similar to the analysis of pleural fluid (see Chapter 8) .

## COMPLICATIONS

The failure of pericardiocentesis to yield fluid ("dry tap") may be considered a complication, as the procedure has failed to achieve its desired result. If a dry tap is considered a complication, it is by far the most frequent one. In addition, the pericardial needle can injure any organ within its reach, causing pneumothorax or myocardial or coronary vessel laceration and, thus, hemopericardium. [114] Venous air embolism may be caused by air entering the heart. [135] The pericardial needle can also induce dysrhythmias from direct irritation of the epicardium or from small currents leaking from the connected ECG machine. [2]

Assessing the frequency of complication from pericardiocentesis is not as simple as it might appear. Changes in diagnosis of effusion by ultrasound and guidance of the procedure by ultrasound or fluoroscopy have greatly reduced the likelihood of complication. [100] [126] For example, Wong

and colleagues reported that most complications occurred in patients who were found retrospectively to have no effusion at all. [3] Unfortunately, ultrasound remains highly operator dependent, and the chances of misadventure are in large part dependent on operator skill. The procedure is also often performed on a moribund patient, and distinguishing between a poor outcome resulting from a poorly performed procedure and a poor outcome resulting from the underlying condition can be difficult.

Six studies summarized in Table 15-4 demonstrate that the risks of pericardiocentesis remain quite significant. The major complications will be discussed individually.

### Cardiac Arrest and Death

Cardiac arrest and death occurred in approximately 2% of patients in the larger series listed in Table 15-4 , but in none of a series of patients whose pericardiocentesis was directed solely by ultrasound. However, an exact causal relationship between pericardiocentesis and sudden death is difficult to substantiate. For example, in one series of 52 patients, the only death occurred in a patient in cardiogenic shock who had a nonproductive pericardiocentesis and who, on postmortem examination, had severe arteriosclerotic heart disease, not tamponade. [3] An additional case of cardiac arrest (successfully resuscitated) in this series was in a patient with a nonproductive pericardiocentesis; the cause of the arrest was not discussed. [3]

In two studies comprising 197 patients who underwent pericardiocentesis under echocardiographic guidance, there have been no cardiac arrests or deaths. [100] [126] In a series of 352 pericardiocenteses performed under fluoroscopic guidance, only two deaths resulted. [4] Ultrasound or CT confirmation of effusion was used in all but 15 cases. The two deaths occurred during or after the procedure, but whether they should be attributed to the procedure is unclear. One patient with aortic rupture penetrating into the pericardial space died of cardiac arrest immediately after the puncture. The other death, in a postmyocardial infarction patient with left ventricular aneurysm, was due to ventricular fibrillation that occurred about 15 minutes after the procedure.

**Cardiac Chamber, Vessel, or Lung Laceration**

Cardiac chamber, vessel, or lung laceration occurs in 6 to 9% of patients, even in the hands of experienced physicians under controlled situations. Nonfatal cardiac puncture, pneumothorax, and pneumoperitoneum have been reported, [45] as well as suppurative costochondritis. Most cardiac perforations occur in the right ventricle, but left ventricular [4] as well as atrial punctures have been reported. [15]

In Krikorian and Hancock's series, 13 of 123 patients developed hemopericardium as a result of pericardiocentesis, 1 as a result of a lacerated coronary artery. [27] One patient died from a punctured ventricle. Surgical control was necessary for 4 patients who developed tamponade, whereas 8 patients with hemopericardium did not develop tamponade and were managed conservatively. Several cases of induced tamponade occurred in patients with platelet counts >50 × 10 [9] /L.

Guberman and coworkers reported 3 right ventricular lacerations in 46 patients; one was fatal. [35] Wong and colleagues found 5 right ventricular punctures, 4 in patients with nonproductive pericardiocentesis, but none causing any adverse sequelae. [3] In a series of dialysis patients, 9 of 10 receiving pericardiocentesis had serious complications, including 3 deaths and 2 myocardial lacerations. [44] Duvernoy and coworkers [4] reported 23 penetrations (all right ventricular except 2 in which the right and left ventricles had been perforated), along with 4 cases of significant arterial bleeding in a series of 352 procedures.

Researchers differ in their opinions as to the adverse effects of ventricular puncture. Most ventricular punctures during the procedure occur in the lower aspect of the right ventricle. Because the pressure is lower there than in the left ventricle, [54] there should be less bleeding; however, the ventricular wall is also thinner and more vulnerable to laceration. In a series of patients whose pericardiocentesis was exclusively directed by ultrasound, ventricular puncture still occurred in 1.5% but was without consequence due to small needle size. [126] In another study, right ventricular laceration occurred in 1 patient despite the use of echocardiography, producing tamponade and necessitating emergency surgery. [100]

* 1.6% indicates directly attributable deaths; 3.2% also includes contributory deaths

Of the 23 perforations in the series by Duvernoy and colleagues, [4] only 3 were considered "major" complications, with 2 of the patients requiring thoracotomy.

A small number of pneumothoraces and pneumopericardium have been reported in various series (see Table 15-4) but have been without clinical consequence. A single case of tension pneumothorax has been reported after pericardiocentesis, but the cause-and-effect relationship was unclear. [136]

**Dysrhythmias**

Serious dysrhythmias induced by pericardiocentesis are rare. Premature ventricular contractions (PVCs) occur commonly during the procedure and are benign in most cases. Wong and coworkers, [3] Guberman and colleagues, [35] Callahan and investigators, [126] and Kwasnik and coworkers [45] reported no dysrhythmias. Krikorian and Hancock reported only one episode of ventricular tachycardia and several "hypotensive vasovagal reactions," which were associated with bradycardia and responded to atropine and fluid loading. [27] Duvernoy and colleagues [4] reported 1 case of ventricular tachycardia and 1 case of atrial fibrillation among 352 procedures.

**Adverse Physiologic Consequences**

There have been a few case reports of adverse consequences even when pericardiocentesis inflicts no injury. Most of these have to do with the fact that during pericardiocentesis, the stroke volume of the previously collapsed right ventricle increases 77% with the first 200 mL of fluid removed. [57] Generally, this increase in stroke volume is greater initially than that demonstrated by the left ventricle. This can have significant consequences for both right and left ventricular function. In 3 of 6 patients in whom large effusions were removed by pericardiocentesis, there was right ventricular dilation and overload, with abnormal septal motion and either no increase in right ventricular ejection fraction or a decrease. [137] These patients returned to normal hemodynamic status slowly.

Sudden pulmonary edema also has been reported after pericardiocentesis, presumably due to a sudden increase in venous return to the left ventricle at a time when peripheral vascular resistance is still high from compensatory catecholamine secretion. [138] [139] [140] Supporting evidence for this explanation is that right ventricular stroke volume increased 76% after relief of tamponade, greater than the stroke volume increase of the left ventricle. [60] Circulatory collapse with persistently low arterial blood pressure has been reported in a patient who was drained of 700 mL of clear fluid at a rate of 100 mL/min. [141] These authors suggest that ketamine anesthesia may have played a role, but the relative ischemia created by tamponade, coupled with the sudden increase in left-sided preload, created a persisting imbalance. They recommend that pericardial drainage rate not exceed 50 mL/min. Given the rare occurrence of pulmonary edema or primary cardiac compromise, it is unclear whether this limitation is justified.

A case of brief profound bradycardia and rebound hypertension has also been reported after surgical relief of tamponade. [142] Such responses have not been noted in large series of patients receiving pericardiocentesis.

## SUMMARY

In *nontraumatic patients,* tamponade should always be considered in the differential diagnosis of shock, especially in patients who are on anticoagulants, who have had recent myocardial infarction, or who have had pericardial disease; when malignancy is present; when aortic dissection is suspected; or when a CVP catheter is in place. Tamponade should also be considered in the differential diagnosis when hypotension

persists following closed-chest CPR or attempts at cardiac pacing.

In any patient with blunt or penetrating chest or upper abdominal trauma, the possibility of *traumatic tamponade* must also be considered. If clinical deterioration occurs in the emergency department pending operative care, temporizing pericardiocentesis should be considered if other therapy fails. When such a patient arrives with no obtainable blood pressure or in profound shock and unconscious, immediate thoracotomy and pericardiotomy are indicated after intubation. [113] [143] [144] Pericardiocentesis may cause a dangerous delay in this situation and has a low success rate.

Management of tamponade requires a sound understanding of pathophysiology; an ever-vigilant evaluation; and the willingness, if necessary, to perform relatively high-risk procedures such as pericardiocentesis in critically ill or injured patients.

## Intracardiac Injection

Because intracardiac injection (ICI) is related procedurally to pericardiocentesis (i.e., both techniques require transthoracic penetration of the pericardium with a needle using similar anatomic approaches), these techniques are presented together. The major difference is that whereas the goal of pericardiocentesis is to stop needle penetration within the pericardial space, ICI requires penetration of the myocardium for delivery of drug directly into a cardiac chamber.

The technique of ICI is occasionally needed for delivery of cardiac resuscitation drugs when other vascular options are not available in a timely manner. Throughout the 1960s, ICI was recommended as the most expeditious route of drug administration during cardiac arrest. [145] [146] In the years that followed, the technique fell into disfavor as alternative (less invasive) routes for drug delivery were validated and the risks associated with ICI were enumerated.

Although ICI is no longer a preferred route for drug administration during resuscitation, it can still be useful in those cases in which prompt IV access is unattainable and when drug administration by other routes has proven ineffective. The technique of ICI is easily taught and requires little equipment. Studies suggest that when properly performed, ICI carries a low risk of clinically significant complications. [147] [148] [149]

### BACKGROUND

The technique of ICI appears to have originated in the latter part of the 19th century. Fantus attributed its first use to a German physiologist, Schiff, around 1880. [150] By 1930, more than 250 case reports, with an overall success rate of approximately

25%, had appeared in the literature. Yet use of ICIs remained controversial. The report of the Special Committee on Intracardiac Therapy of the Witkin Foundation, published in 1930, concluded that the beneficial effect of intracardiac injection was not from the medication itself, but from the irritant effect of the needle on the myocardium. [151] This concept remained popular until 17 years later, when Beecher and Linton reported a

case of intraoperative cardiac arrest that failed to respond to repeated right atrial punctures until two injections of epinephrine into the right atrium restored a normal sinus rhythm. [152] They concluded that the epinephrine, and not the puncture itself, was responsible for the successful resuscitation.

By the mid-1950s, intracardiac epinephrine had become part of the standard treatment for cardiac arrest, [146] [153] and with the advent of closed-chest cardiac massage in the 1960s, the intracardiac route of drug administration remained popular. [154] [155] [156] By the mid-1970s, the popularity of ICI had declined. Goldberg warned of the numerous potential complications and advised against the use of ICI, except when it was "absolutely necessary" or during open chest cardiac massage. [157] Schechter, in 1975, harshly condemned the ICI of epinephrine and stated that the technique has been obsolete for about 20 years." [158]

The primary reasons for the decline in the use of ICI seem to be as follows:

1. Serious complications resulting from ICI have been well documented. [154] [157] [159]
2. Safe and simple percutaneous techniques have been developed that allow entry into the central venous circulation.
3. Experimental evidence suggests that ICI offers no advantage over injection into peripheral veins. [160]
4. The endotracheal [161] [162] and intraosseous [163] [164] [165] routes of drug administration have been validated.
5. Interruption of CPR during the performance of ICI was thought to be too prolonged. [157] [166]

Although ICI use is seldom reported in the United States, published reports of its use elsewhere continue. In 1990, a Danish trial reported on 543 ICIs in 247 patients using the parasternal approach. [149] The authors concluded that "the risk of ICI with proper technique is sufficiently low to warrant its use during cardiac arrest."

## INDICATIONS AND CONTRAINDICATIONS

Evidence favoring the intracardiac route of injection is theoretical or anecdotal, with several authors suggesting that ICI of epinephrine may be more effective than IV epinephrine in treatment of asystole or electromechanical dissociation. [166] [167] [168] [169] To date, no experimental or clinical data suggest an advantage with the intracardiac drug delivery route during cardiac resuscitation. Thus, the primary indication for ICI is when other vascular access routes for drug administration are not available in a timely manner. A possible secondary indication for ICI is when other forms of drug administration, particularly endotracheal therapy, [170] have failed to resuscitate the patient. In these circumstances a trial of ICI administration would seem warranted.

In the circumstances discussed above, there are no true contraindications to this technique. Certain associated conditions, such as the presence of a preexistent pneumothorax or the hyperinflated chest of chronic lung disease, make the procedure more difficult and may alter the chosen approach. Anticoagulation has been shown to be associated with a greater incidence of hemopericardium, but this rarely results in

hemodynamic embarrassment. [156]

## EQUIPMENT AND DRUGS

Prefilled syringes intended for intracardiac injection are no longer available in the United States. As a result, an 18-ga spinal needle fitted to the end of a regular medication syringe is the best choice for ICI. Spinal needles of narrower gauge may be used, but they are more prone to bending and occlusion by tissue plugs. The primary agent used for ICI is epinephrine (1 mg for adults; 0.01 mg/kg as an initial dose for children). When children are unresponsive to the initial dose, 0.1 to 0.2 mg/kg may be administered. Generally a 1:10,000 epinephrine concentration (1 mg in 10 mL) is used. However, when the higher dose is used for children unresponsive to an initial dose, a 1:1000 concentration (1 mg in 1 mL) is preferred.

## PROCEDURE

Both the subxiphoid and parasternal approaches have been recommended as the primary approach for ICI. The parasternal approach has the advantage of a shorter, more direct route but appears to suffer from a higher rate of complications, particularly pneumothorax. This finding differs from data specific to pericardiocentesis and may be the result of differences in patient positioning during the procedure, changes in cardiac positioning with and without pericardial effusion, or the effects of cardiac arrest and ongoing CPR.

The techniques used for ICI are similar to those used for pericardiocentesis. They differ primarily in setting and the need for ECG or imaging guidance. Whereas pericardiocentesis often takes place with the patient awake and responsive, ICI always occurs with ongoing CPR and for this reason must be done as rapidly as possible to avoid prolonged cessation of CPR. Whereas the goal in pericardiocentesis is to avoid contact with the heart, ICI aims to penetrate the heart. As a result, there is no need for ECG or ultrasound guidance.

**The Subxiphoid Approach**

The technique and landmarks are the same as in pericardiocentesis. Without interrupting CPR, the left costoxiphoid area is prepared with an antiseptic solution. The syringe with the drug to be injected is freed of all air bubbles. At this point, the lungs are allowed to deflate, and CPR maneuvers are stopped. With the bevel up, the tip of the needle is inserted in the xiphocostal notch (approximately 1 cm to the left of the tip of the xiphoid process). The needle is directed cephalad toward the middle of the left clavicle at a 30° to 45° angle with the skin of the abdominal wall (Fig. 15-15) .

Some operators prefer to keep the obturator in the spinal needle until skin puncture has been completed, thus reducing the likelihood of obstructing the lumen with a skin plug. After skin puncture, the syringe is attached and the plunger gently depressed to expel any air in the needle. This technique should not be used when tissue-toxic fluids (e.g.,

**Figure 15-15** Subxiphoid approach to right ventricle for intracardiac injection. It is suggested that the needle be aimed toward the *mid* left clavicle. This figure shows the needle aimed toward the *medial* left clavicle. *A,* Frontal view. *B,* Lateral view. Note the proximity of the stomach and liver to the entrance point.

calcium chloride or sodium bicarbonate) or high-concentration epinephrine (1:1000 concentration) are used.

After the needle has penetrated into the SQ tissue, gentle constant negative pressure is applied to the syringe, and the needle is advanced rapidly. When blood spurts into the syringe, needle advancement is stopped, and the medication is injected as quickly as possible. The needle is withdrawn immediately, and CPR is resumed. *An intracardiac injection should not interrupt CPR for >5 to 10 seconds.* If, after full insertion of the needle, there is no blood return, the needle must be withdrawn immediately, and CPR must be resumed before another attempt is made. The clinician may then attempt penetration again, this time with the needle directed straight up toward the suprasternal notch. If this fails, a third attempt with the needle directed toward the mid-right clavicle is recommended. If this is also unsuccessful, the left parasternal approach should be tried.

**The Left Parasternal Approach**

This approach is completed similarly to pericardiocentesis, but both the fourth and fifth left intercostal spaces may be used. The selected space along the sternal border is prepared with antiseptic solution. After the lungs are allowed to deflate passively, the needle is inserted just over the fifth or sixth rib, immediately lateral to the sternum (see Fig. 15-11) . While gently aspirating with the syringe, the clinician rapidly advances the needle dorsally with slight medial and cranial elevation until an abrupt blood return is observed. [146] [171] At this time the medication is injected as rapidly as possible, the needle is withdrawn, and CPR is resumed immediately.

**Intracardiac Injections in Infants and Children**

The injection technique for infants and children is essentially the same as that for adults. Both the left parasternal and the subxiphoid routes may be used. The chest wall in children is thinner and more pliable than in adults, and injection with a 20- or 22-ga spinal needle has been recommended. [172] [173]

## COMPLICATIONS

As described in the introduction, a major objection to the use of ICI has been the potential for complications. Although case reports of several complications exist, clinical series have failed to document frequent problems (Table 15-5) .

**Coronary Artery Laceration**

Coronary artery laceration is a frequently mentioned potential complication of ICI. Although lacerations have been reported in animal experiments and in human cadaver studies, [13] [174] reports of laceration during resuscitation have been largely anecdotal. [175] Saphir found no coronary artery lacerations at autopsy in 62 patients who had received a total of 155 ICIs during unsuccessful resuscitation attempts. [156] Table 15-5 illustrates further series where only 1 coronary laceration was noted among a total of 842 patients receiving ICI.

**Hemopericardium**

In contrast to coronary laceration, hemopericardium appears to be relatively common following ICI and may lead to tamponade. In a series of left ventriculographies using the intercostal approach, Bjork and colleagues found four instances of hemopericardium among 27 patients who underwent surgery following cardiac puncture. [176] In the same series were six instances of cardiac tamponade among 138 patients. Lehman found three instances of tamponade in more than 300 patients receiving transthoracic ventriculography by the subxiphoid approach. [177] Saphir reported 9 cases

of hemopericardium at autopsy in 62 patients following unsuccessful CPR and noted that this complication was associated with ICI. [156] Davison and coworkers found evidence of hemopericardium in 12 of 39 patients by echocardiography or postmortem examination but no clinical evidence of tamponade in 29 survivors. [147] Jespersen and colleagues [149] found only 3 cases of hemopericardium, with no tamponade attributable to ICI among 182 autopsies following unsuccessful resuscitation, but the series included 24 patients with tamponade due to cardiac or aortic rupture.

**Pneumothorax**

Intuitively, one would expect pneumothorax to be a common occurrence following ICI, particularly when using the left parasternal approach. The studies summarized in Table

15-5 bear this out, with the rate of pneumothorax among patients with parasternal ICI being 10.3% (24/233) as compared to 2.0% (3/148) among patients with subxiphoid ICI. Although pneumothorax can result from CPR alone, in the study by Amey and colleagues, 3 of 29 patients receiving ICI developed a pneumothorax, compared with only 1 of 64 who did not receive ICI during CPR. [148]

**Intramyocardial Injection**

The intramyocardial injection of contrast material has been associated with intractable ventricular fibrillation and death. [177] The combined results of 2 ventriculography series involving the subxiphoid approach showed that 4 of 434 patients underwent intramyocardial injections with subsequent ventricular fibrillation. [177] [178] This situation is probably not comparable with ICI performed during CPR, when the heart is not beating and injection must be made without the benefit of fluoroscopic guidance. It is unlikely that the true incidence of this dire complication, which may result in the same rhythm as that originally being treated, will ever be known.

**Other Potential Complications**

Laceration of other organs is a potential complication that has rarely been reported as a consequence of ICI during human resuscitation. The subxiphoid approach brings the injecting needle close to the stomach and the left lobe of the liver. Smith and colleagues reported hepatic laceration during subxiphoid injection in dog experiments. [179] Although Brown and coworkers [13] reported 14 liver punctures in cadavers following 60 subxiphoid pacemaker insertions, there have been no reports of liver or stomach laceration resulting from the clinical use of ICI. Brown and associates also found a high incidence of inadvertent right atrial puncture that complicated the subxiphoid approach. [13] Based on evidence from clinical studies, it appears that this complication is either rare or of little clinical significance during human resuscitation. [147] [148] [174]

Punctures of the pulmonary artery and aorta have been reported by Sabin and coworkers following atypical parasternal approaches utilizing the second or third intercostal space. [174] Other potential complications include infection and air embolism. Although Bodon in 1923 described a case of fulminant pericarditis following intracardiac injection, [180] no subsequent incidence of pericarditis or endocarditis has been documented. Similarly, air embolism has not been reported.

Careful attention to technique minimizes the risk of some of these complications. To further minimize potential complications following a successful resuscitation, a chest film should be examined for evidence of pneumothorax and the patient observed for signs of hemopericardium or tamponade.

The most common error in technique, and the one stated by the American Heart Association [166] as the major hazard related to ICI, is the prolonged interruption of CPR associated with the procedure. Repeated attempts at ICI after an initial failure *without the reinstitution of CPR* should be avoided.

**SUMMARY**

For more than 100 years, the intracardiac route has been used to deliver medication during cardiac arrest. Although the technique has been shown to be effective, its popularity has declined because of the availability of other effective routes for drug administration and the fear of potential

complications. A review of the literature suggests that these fears are overstated. Although intracardiac puncture is not recommended as the initial route of injection when other vascular access options exist, it should be retained as a valid technique for the administration of emergency drugs during CPR when other routes are not readily available.

# Chapter 16 - Artificial Perfusion During Cardiac Arrest

**Carol S. Federiuk**

**Arthur B. Sanders**

The modern era of cardiopulmonary resuscitation (CPR) was introduced by Kouwenhoven and colleagues [1] in 1960 in a classic paper that brought together the concepts of mouth-to-mouth ventilation, closed-chest compression, and external defibrillation. An increased understanding of the mechanism of blood flow during CPR has led to periodic revision of the recommended standards for CPR and to development of alternative methods of CPR. This chapter discusses the current understanding of the mechanism of blood flow during CPR, standard and alternative techniques of CPR, and methods for evaluating these techniques by assessing perfusion during CPR.

## BACKGROUND: MECHANISM OF BLOOD FLOW

The mechanism of blood flow during CPR has been the subject of much debate since the 1960s. Two mechanisms for blood flow have been proposed: the "cardiac pump" model and the "thoracic pump" model. The current concept of blood flow during CPR is based on these models and provides the theoretical basis for the newer CPR techniques.

Kouwenhoven and colleagues, in their 1960 paper, proposed the traditional cardiac pump mechanism of blood flow. [1] Pressure on the chest compresses the heart between the sternum and the vertebrae, forcing out blood (Fig. 16-1) (Figure Not Available) . [2] The relaxation phase of CPR allows the heart to fill. This model assumes that compression of the ventricles raises intraventricular pressure above that of the aorta and pulmonary artery, creating a pressure gradient that generates forward blood flow. Closure of the atrioventricular valves during chest compression was thought to prevent retrograde blood flow.

The cardiac pump model of blood flow has been the subject of much debate since its introduction. Weale and Rothwell-Jackson, in 1962, showed that chest compression induces almost equivalent increases in arterial and venous pressures in animals. [3] They hypothesized that closed-chest compression creates a generalized increase in intrathoracic pressure that is transmitted equally to the heart and intra- and extrathoracic vessels, because the atrioventricular valves remain open (Fig. 16-2) (Figure Not Available) . [2]

Multiple studies have been published in support of each of these models. Additional evidence for the thoracic pump model has been provided by the reported success of cough CPR. Several studies of simultaneous compression and ventilation also have suggested that increases in intrathoracic pressure produce forward flow of blood. The direct cardiac compression model has received additional support from echocardiographic studies. The data in support of each of these models have been

summarized elsewhere. [4]

Although the debate over the exact mechanism of blood flow during CPR persists, Maier and associates shed light on the subject in their study of the effect of varying the rate, force, and duration of compressions in CPR on large dogs. [5] These investigators demonstrated that the relative contribution of the thoracic pump and direct cardiac compression models to blood flow varied with the CPR technique used. Direct cardiac compression predominated when chest compressions were delivered at higher rates (high-frequency CPR), and the thoracic pump mechanism predominated in low-momentum compression techniques, such as simultaneous compression and ventilation (SCV) CPR. In addition, Babbs and coworkers noted that the optimal technique of CPR varied with the size of the experimental animal and the size of the pad performing chest compressions. [6] Large animals in arrest were more likely to benefit from SCV CPR than smaller animals. Direct cardiac compression was proposed to play a greater role in smaller animals.

In summary, the mechanism of forward blood flow during closed chest compression appears to be multifactorial, with dependence on several factors:

1. Body size of the patient
2. Chest configuration, particularly anteroposterior diameter
3. Previous thoracic surgery
4. Molding of the chest with continued CPR
5. Size of hand or paddle performing chest compressions
6. Rate and force of chest compressions

Knowledge of the mechanisms of blood flow during CPR may allow the clinician to use alternative techniques that provide better perfusion pressures during cardiac arrest. The optimal technique for CPR may not be the same in every patient. For example, obese patients with large anteroposterior diameters may benefit more from SCV; thin patients may benefit from faster compression rates. The key to clinical implementation of these changes is being able to assess perfusion during ongoing CPR. Advances in this area are discussed later in this chapter.

## STANDARD CPR TECHNIQUE

Guidelines for the performance of CPR have been recommended by the American Heart Association and are revised periodically to reflect ongoing research. [7] Current guidelines are summarized in Table 16-1 .

External chest compression is performed over the lower half of the sternum, compressing the sternum 3.8 to 5.0 cm in the normal-sized adult. The pressure is released completely after each compression, and an equivalent amount of time is allotted for relaxation as for compression. The chest compression rate is 80 to 100 per minute. Two ventilations are given after each 15 chest compressions in one-rescuer CPR, and 1.5 to 2.0 seconds are allowed for each breath in order to provide good chest expansion. In two-rescuer CPR, one ventilation is performed after every 5 compressions during a 1.5- to 2.0-second pause. Once the patient is endotracheally intubated, the

rescuer need not stop compressions for the ventilatory pause. Rather, ventilation should be performed asynchronously at a rate of 12 to 15 per minute.

In children, compressions are performed with the heel

of one hand placed 2 fingerwidths above the xiphoid process. The chest is compressed to a depth of 2.5 to 3.8 cm at a rate of 100 per minute. At the end of every fifth compression, a 1- to 1.5-second pause is allowed for ventilation in both one- and two-rescuer CPR.

Chest compressions in infants currently are performed 1 fingerwidth below the intramammary line. The chest is compressed with 2 to 3 fingers to a depth of 1.3 to 2.5 cm. The recommended compression rate in infants is at least 100 per minute. A 5:1 compression-to-ventilation ratio is maintained for both one- and two-rescuer CPR.

The preferred technique for performing chest compressions in the neonate involves encircling the chest of the neonate with the rescuer's hands and compressing the sternum just below the nipple line with the two apposed thumbs. If the rescuer's hands are too small to encircle the

| TABLE 16-1 -- Standard CPR Guidelines | | | | |
|---|---|---|---|---|
| | Adult | Child | Infant | Neonate |

| Rate of compression (per min) | 80-100 | 100 | 100 | 120 |
|---|---|---|---|---|
| Compression depth | 1.5-2 in. | 1-1.5 in. | 0.5-1 in. | 0.5-0.75 in. |
| Compression duration | 50% of cycle | 50% of cycle | 50% of cycle | 50% of cycle |
| Compression mode | Both hands | Heel of one hand | 2-3 fingers | Apposed thumbs |
| Compression-to-ventilation ratio | 15:2 (1 rescuer) | 5:1 (1 rescuer) | 5:1 (1 rescuer) | 5:1 (1 rescuer) |
| | 5:1 (2 rescuers) | 5:1 (2 rescuers) | 5:1 (2 rescuers) | 5:1 (2 rescuers) |

chest, compressions may be performed with the ring and middle fingers 1 fingerwidth below the intramammary line. The sternum of a neonate is compressed 1.3 to 2.0 cm at the rate of 120 per minute. Chest compressions are interposed with pauses for ventilation in a 3:1 ratio.

## MECHANICAL DEVICES FOR STANDARD CPR

Mechanical resuscitators have been developed that can provide standard chest compressions and ventilations during CPR. Clinical studies have demonstrated that mechanical CPR devices are comparable to standard manual CPR. [8] [9] [10] The advantages of mechanical devices include controlled, constant chest compressions; the elimination of operator fatigue; and the freeing up of personnel to perform other functions. The device currently in most common use is the Thumper Cardiopulmonary Resuscitator (Michigan Instruments, Inc., Grand Rapids, MI).

**The Thumper**

The Thumper is a gas-powered mechanical device that is in relatively broad use. This device consists of a compressed gas-powered plunger mounted on a backboard and a

time-pressure cycled ventilator (Fig. 16-3 *A* and *B*).

The Thumper delivers chest compressions at rates consistent with American Heart Association (AHA) guidelines with a compression duration that is 50% of the cycle length. Every fifth compression is followed by a ventilation at an adjustable airway pressure. The Thumper can be driven by wall oxygen at 50 psi or by standard portable oxygen tanks.

**Setup of the Thumper**

The Thumper can be positioned from either side of the patient. Care should be taken to ensure that the base plate is positioned horizontally under the patient's posterior thorax with the patient lying near the center of the base plate. After the cylindric column and piston are fitted on the base plate, the piston pad position should be adjusted so that the pad lies over the lower one third of the sternum. The compressor piston is positioned after the oxygen hose has been connected; therefore, CPR is not interrupted during assembly of the Thumper. The piston column is calibrated with rings; each ring indicates 1.25 cm of piston excursion. Before the device is started, the piston height should be adjusted so that 1 ring is just visible on the piston column. With the Thumper operational, chest compressions should be adjusted to 5 to 6.25 cm ("4 rings" of sternal displacement) or 20 to 25% of the patient's anteroposterior chest diameter, once the machine is in operation. The device should not be set to function at a predetermined chest compression force.

The ventilation hose can be connected to an endotracheal tube, an esophageal obturator, or a face mask. Airway pressure should be adjusted to 40 to 50 cm $H_2O$ during ventilation as displayed on the airway pressure gauge when the patient is intubated. Otherwise the airway pressure limit should be set at 30 cm $H_2O$ to avoid gastric distention. Airway pressure is maintained for 1.5 to 1.8 seconds.

Use of the Thumper requires operation of 3 key switches: the main on/off switch, the ventilation on/off switch, and the piston activator switch. When a pause in compressions is required for other procedures, the operator can easily stop compressions by turning off the third switch. Subclavian or jugular central lines can be placed with the Thumper in position, although it is recommended that the device be turned off during needle advancement to avoid arterial or lung injury. Defibrillation should be performed during the compression phase, when thoracic impedance is minimized.

## ALTERNATIVE CPR TECHNIQUES

Modifications of the standard CPR technique have been proposed since the 1980s. Although each technique has initially been promising when investigated in one or two laboratories, and although some have demonstrated potential advantages in small clinical trials, insufficient clinical evidence exists for widespread implementation of these techniques over standard CPR at this time.

## Simultaneous Compression

and Ventilation CPR

The SCV method of CPR was designed to take advantage of the thoracic pump mechanism of forward blood flow. It maximizes intrathoracic pressure by generating a high airway pressure during the compression phase of chest massage. During the relaxation phase, the airway pressure is released. SCV has been shown to improve arterial pressure and carotid blood flow in some animal studies. [11] Because SCV CPR has not been demonstrated to have a beneficial effect on clinical outcome, the technique should be regarded as experimental. [12]

## Interposed Abdominal Compression CPR

The technique of interposed abdominal compression (IAC) CPR interposes abdominal compressions between the chest compressions of CPR (Fig. 16-4) (Figure Not Available) . [13] [14] [15] CPR is performed using American Heart Association guidelines; however, during

**Figure 16-3** The Thumper is an oxygen-powered device which is capable of providing the chest compressions and ventilations required during CPR. *A,* The device consists of a back plate with a cylindric column. On the column fits the sliding arm, with the compressor piston to be positioned over the lower sternum. The force of chest compression is adjustable, and defibrillation can be easily performed with the device in place. *(With permission of Dixie, USA.)B,* To apply the Thumper to the cardiac arrest patient, position the base assembly under the patient's back and snap the column and arm onto the base. Attach the oxygen supply and breathing circuit to the Thumper. Provided there are adequate personnel, manual CPR can be continued from one side of the patient while the Thumper is set up on the opposite side.During a pause in manual chest compressions the massager pad of the Thumper is swung into position over the patient's sternum. For positioning the massager onto the patient's chest, numbering on the back of the column prescribes a sternal deflection of 20% of the anterior-posterior chest diameter of the patient being treated. Depth of compression is easily monitored through a clear, graduated, plastic dome which houses the compression piston. Ventilations are delivered via a time-cycled, pressure-regulated ventilator which is synchronized to deliver one breath following each fifth chest compression. Maximum ventilation pressure is adjustable from 0 to 60 cm $H_2O$. The breathing circuit on the unit can be attached to a mask, endotracheal tube, or other airway management devices. Compressions and/or ventilations can be easily paused and restarted.The Thumper is factory set to deliver 80 compressions per minute with a 1:1 compression-to-relaxation ratio. The ventilator is set to deliver a 1.6-second inspiratory time and deliver a breath with each fifth chest compression. The compression rate and ventilation time can be adjusted should standards or local directives change.The Thumper is easily operated using the 5 controls on the unit, which are clearly marked with numbers 1 through 5. The five controls have the following functions.

> #1 opens the master valve and begins pneumatic cycling of the unit. A clicking sound is heard at the pre-set chest compression rate.

> #2 allows gas flow to the dome and compression piston.

> #3 is used to adjust the depth of compression.

the relaxation phase, the abdomen is compressed. Some investigators recommend using a partially inflated, folded blood pressure cuff connected to a transducer to monitor abdominally applied pressure (goal, 120 to 150 mm Hg). Babbs notes that the method of abdominal compression may impact the effectiveness of this technique; he recommends administering abdominal compressions from the victim's left side with the heel of the rescuer's right hand placed just above the umbilicus and centered 3 cm to the left of the abdominal midline. [16]

Several animal studies have demonstrated that IAC CPR increases arterial systolic and diastolic pressures, cardiac output, and the arteriovenous diastolic pressure difference (i.e., coronary perfusion pressure [CPP]) when compared with standard CPR. [13] [14] [15] Despite these results, IAC CPR has not been shown to improve *survival* in animal studies. [17] In humans, IAC CPR inconsistently improves the diastolic CPP. [18] One early study of IAC CPR vs standard CPR on patients treated out of hospital by paramedics following endotracheal intubation found no difference in resuscitation rates. [19]

More recent clinical studies have demonstrated promise for the use of IAC CPR for patients in cardiac arrest. Ward and colleagues showed significantly higher end-tidal $CO_2$ levels (an indirect measure of cardiac output during CPR)

**Figure 16-4** (Figure Not Available) An artist's conception of basic rescuers performing interposed abdominal compression CPR. For clarity, both rescuers are shown on the same side of the victim. With two rescuers, the first compresses the chest and performs ventilation while the second compresses the abdomen. With three rescuers, ventilation, chest compression, and abdominal compression are performed by separate individuals. Ideally, the rescuer performing chest compressions is on the victim's right side and the rescuer performing abdominal compressions is on the victim's left side. *(From Voorhees WD, Niebauer MJ, Babbs CF: Improved oxygen delivery during cardiopulmonary resuscitation with interposed abdominal compressions. Ann Emerg Med 12:128, 1983. Reproduced by permission.)*

when IAC CPR was compared to standard CPR. [20] Sack and coworkers evaluated IAC CPR in a randomized controlled trial of in-hospital cardiac arrest; patients who received IAC CPR had a significantly greater rate of return of spontaneous circulation (51% vs 27%) and hospital discharge (25% vs 7%) compared to patients receiving standard CPR. [21] In another 143 in-hospital patients with asystole and electromechanical dissociation, those patients receiving IAC CPR had significantly greater rates of return of spontaneous circulation (49% vs 28%) and 24-hour survival (33% vs 13%). [22]

**High-Frequency (Rapid Manual) CPR**

Rapid manual CPR uses standard CPR techniques, but chest compressions are performed at a rate of 120 per minute. Maier and colleagues demonstrated that increasing the compression rate to 120 compressions per minute in an animal model

resulted in increased cardiac output, aortic pressure, and coronary blood flow. [5]

Canine studies by Feneley and associates demonstrated that a compression rate of 120 per minute resulted in improved resuscitation and higher 24-hour survival rate compared with a compression rate of 60 per minute. [23] Swart and coworkers demonstrated that at a compression rate of 100 per minute, shorter compression duration (i.e., duty cycles less than 50% or "high-impulse" CPR) also improved resuscitation hemodynamics. [24] The relative merits of high-frequency versus high-impulse techniques remain to be determined, although considered intuitively, a shorter compression duration (high-impulse CPR) would permit greater cardiac filling during high-frequency CPR.

Kern and colleagues studied rapid manual CPR in 23 patients in cardiac arrest; they found that patients who had CPR with chest compression rates of 120 per minute had slightly higher levels of end-tidal $CO_2$ excretion (15 ± 2 vs 13 ± 2 mm Hg) compared to patients with chest compression rates of 80 per minute. [25]

**Vest CPR**

Mechanical devices have been developed to simulate "cough CPR" in the animal model. The vest or binder device produces pulsatile simultaneous increases in intrathoracic, intra-abdominal, and airway pressure through simultaneous inflation of a pneumatic vest, abdominal binder, and endotracheal tube. Niemann and coworkers demonstrated improved hemodynamics and 24-hour survival for those animals receiving vest/binder CPR compared with standard CPR. [26] In contrast, Kern and colleagues could find no improvement in resuscitation or 24-hour survival when vest CPR was compared with standard mechanical CPR. [27] Similarly, lack of benefit was demonstrated in one out-of-hospital cardiac arrest study. [28]

Recently a new mechanical device (vest CPR) has been developed to provide intermittent circumferential compression of the chest through a pneumatic system (Fig. 16-5) . [29] In arrest patients, vest CPR delivered with this device significantly increased peak aortic pressure and CPP when compared with standard CPR. After prolonged unsuccessful standard CPR, despite improved return of spontaneous circulation with the vest, there were no long-term survivors. [29]

**Active Compression-Decompression**

The concept of active compression-decompression (ACD) CPR was based on a case report in which a patient was resuscitated from cardiac arrest with the aid of a plumber's helper. [30] The application of a suction device to the chest wall of a patient in cardiac arrest converts the relaxation phase of standard CPR to one of active decompression. A device based on the principle of active decompression following compression has been developed (Fig. 16-6) and has shown improved hemodynamics in experimental models. [31] The application of this device to humans in cardiac arrest has shown promise in some settings but no improvement in other settings. [32] [33] [34] [34A]

**Chest Compression-Only CPR**

The role of ventilation in bystander CPR is being reassessed. Many people, including health care professionals, have concerns about performing mouth-to-mouth ventilation. [35] [36] [37] While no authority advocates that health care professionals not perform ventilation with CPR, some believe that more laypersons would learn and perform CPR if it involved only chest compressions.

In an animal model of cardiac arrest, Berg and colleagues found no difference in resuscitation, 24-hour survival, or neurologic outcome when comparing 12 minutes of chest compressions alone vs treatment with chest compressions and ventilations. [38] Studies on chest compression-only CPR in humans are limited.

Bossaert and colleagues found that when good-quality chest compression-only CPR was performed on out-of-hospital cardiac arrest patients, there was no difference in long-term survival when compared to chest compression and ventilation CPR (15% vs 12%). [39] Similarly, Van Hoeyweghen and coworkers retrospectively found that only 10% of out-of-hospital arrest patients who received chest compression-only CPR survived long term. This compares with a 16% survival rate for patients receiving good-quality chest compressions

**Figure 16-5** A comparison of vest CPR and standard manual CPR. With vest CPR, a pneumatic system inflates and deflates a bladder surrounding the chest. The compression phase results in circumferential compression as opposed to point compression during manual CPR. The vest CPR system is equipped with defibrillator electrodes that monitor the patient's electrocardiogram as well as allow defibrillation without removal of the vest.

and ventilations, and a 7% survival rate when no bystander CPR was performed.

## ASSESSMENT OF ONGOING CPR

**Quality of CPR**

The assessment of ongoing CPR efforts is crucial in efforts to resuscitate patients in cardiac arrest. Studies have called into question the quality of CPR as currently performed. Kern and colleagues noted in a study comparing two compression rates that the most improvement in end-tidal $CO_2$ excretion occurred before and after audiotones were used to guide compressions. Mean end-tidal $CO_2$ level significantly increased after audiotone guidance was begun (9 ± 1 vs 14 ± 1 mm Hg). [25] Milander and coworkers found that few in-hospital cardiac arrest patients had chest compression performed at rates within AHA guidelines. [41] In a laboratory study assessing compliance with AHA guidelines, CPR-certified health care professionals showed dramatic improvement in adherence to CPR guidelines and in subject end-tidal $CO_2$ levels with use of audiotones. [41] These studies imply that CPR is often not performed according to AHA

guidelines.

The importance of the quality of CPR efforts was emphasized in 2 European studies and 1 U.S. study. Bossaert and colleagues demonstrated that bystander CPR with correct technique and good effect was more effective in producing long-term survival than CPR with bad technique or weak effect. [39] Van Hoeyweghen and coworkers also demonstrated that patients who received correct CPR had significant improvement in long-term survival (16% vs 4%) compared to patients with incorrect CPR and patients with no bystander CPR (16% vs 7%). [40] Gallagher and colleagues found an odds ratio of about 4:1 in favor of hospital survival when out-of-hospital CPR by bystanders was judged as having both effective compressions and ventilations (independent of initial rhythm and intervals from resuscitation). [42]

## Assessment of Ongoing CPR

The prognosis for resuscitation of patients in cardiac arrest depends on the no-flow interval before CPR is initiated, the time interval from collapse to defibrillation (if the rhythm is ventricular fibrillation), and the initial cardiac rhythm. Once the resuscitation efforts are initiated, there is no ideal criterion to judge the efficacy of CPR. In most animal and clinical studies, outcome (i.e., resuscitation or death) is the only

**Figure 16-6** The active compression-decompression (ACD) device uses a suction cup positioned at mid-chest at the level of the nipples. The device is pushed downward into the chest during the compression phase of CPR. The force of compression can be approximated by the gauge within the handle. During the decompression phase, the handle is actively pushed up and away from the chest while the suction keeps the device attached. This active withdrawal characterizes the decompression phase of CPR. The value of this adjunct is uncertain.

criterion used. Recent studies in the literature have focused attention on the problem of assessing effectiveness of ongoing resuscitation efforts.

### Hemodynamics

Studies in experimental arrest models have demonstrated the importance of the aortic diastolic pressure and CPP for successful resuscitation. [43] Redding, in a series of classic experiments, showed that the aortic diastolic pressure must be raised >40 mm Hg to successfully resuscitate animals in cardiac arrest. [44] He suggested that alpha-catecholamine agents were crucial for resuscitation, because they help raise the aortic diastolic pressure. [45] Animals without vascular disease can be resuscitated even after 30 minutes of ventricular fibrillation, providing the aortic diastolic pressure and CPP are maintained at adequate levels. [46] Coronary blood flow has been shown to correlate well with the diastolic CPP. [47]

Although data confirming these observations are limited for humans undergoing CPR, one can extrapolate that CPR will be most effective when it provides adequate myocardial perfusion. In the setting of cardiac arrest, coronary blood flow and myocardial perfusion are directly related to the CPP. Paradis and colleagues measured

the CPP in 100 patients with cardiac arrest during CPR. Patients with return of spontaneous circulation had significantly higher maximal CPP (25.6 ± 7.7 vs 8.4 ± 10.0 mm Hg) compared to those who died. No patient with a maximal CPP <15 mm Hg had return of spontaneous circulation. [48] However, in patients with severe coronary artery obstruction, it may be impossible to generate adequate blood flow to some areas of the myocardium with CPR.

In summary, the aortic diastolic pressure and CPP appear to be the best available criteria for assessing perfusion during CPR and correlate with survival in animal models. Thus, the clinician should attempt to optimize these hemodynamic parameters during CPR. However, in most practice settings, the clinician will not have the opportunity to directly measure aortic and right atrial pressures during CPR. Therefore, simpler, less invasive parameters are needed to guide resuscitation efforts in most patients suffering cardiac arrest.

**Arterial Blood Gases**

Clinicians often use arterial blood gas values to confirm the adequacy of their CPR efforts. Studies in experimental models have not shown a correlation between arterial blood gas values and successful resuscitation. [49] Physiologically, one would not expect the arterial pH, $P_{O_2}$, and $P_{CO_2}$ to reflect tissue perfusion pressures. In fact, patients who suffer sudden ventricular fibrillation with no systemic perfusion will have normal aortic pH, $P_{O_2}$, and $P_{CO_2}$ for several minutes following the arrest.

More recently, attention in the literature has focused on mixed venous gases. In the setting of cardiac arrest, venous gases will frequently show severe hypercarbia and acidosis, while arterial blood gas values are relatively normal. [50] The extent of this venous-arterial $P_{CO_2}$ gap may be reflective of poor perfusion pressures. Evaluation of the venous-arterial $P_{CO_2}$ gap, however, must be considered an experimental technique.

**Pulses**

Another commonly used technique for assessing the adequacy of CPR efforts is the presence or absence of femoral or carotid pulses. There are no studies indicating the clinical utility of pulses during CPR. The pulse represents a pulse pressure or the systolic-to-diastolic pressure gradient and does not reflect the CPP. In addition, reliance on femoral pulses can be misleading. Since there are no valves in the inferior vena cava, blood frequently flows in a retrograde fashion to the lower half of the body during chest compression. Thus, a *palpable femoral pulse may represent venous rather than arterial blood flow*. The presence of carotid pulses may indicate some forward blood flow with chest compression. However, the extent of blood flow and, more important, tissue perfusion cannot be gauged by the presence or absence of a pulse.

**Capnometry**

Capnometry has been evaluated for monitoring ongoing CPR efforts. Capnometers use infrared spectroscopy to measure $CO_2$ in exhaled air. The sensor or sampling port is

attached to the endotracheal tube. Carbon dioxide concentration in exhaled air is dependent on (1) its production by systemic metabolism; (2) its circulation, specifically pulmonary blood flow or cardiac output; and (3) the ventilatory system for excretion. In the setting of cardiac arrest and CPR, in which systemic metabolism and ventilation are held relatively constant, exhaled $CO_2$ reflects primarily lung perfusion and cardiac output.

In the experimental model, end-tidal $CO_2$ concentration during CPR correlates well with cardiac output and CPP. [51] [52] Studies in animal models have shown that $CO_2$ monitoring during CPR can distinguish those animals who will be successfully resuscitated from those that die. [53] [54] There have been few studies evaluating the clinical use of capnometry

for monitoring patients in cardiac arrest. Kalenda reported three patients who suffered cardiac arrest while being monitored by capnometry. [55] He found that when a rescuer fatigued while performing CPR, $CO_2$ concentration fell; however, $CO_2$ concentration promptly increased again when a fresh rescuer took over. These observations suggest using capnometry as a prognostic guide to ongoing resuscitation.

**Indications.**

Although capnometry remains an experimental technique, it shows promise as a means of noninvasively monitoring perfusion during CPR. Animal [54] and clinical studies [56] [57] suggest that increased $CO_2$ concentration may be the first indicator of restoration of spontaneous circulation. Capnometry also may prove helpful for quantifying the probability of developing a perfusing rhythm as a result of resuscitative efforts. The technique is relatively contraindicated only when pharmacologic therapy may affect proper interpretation of the resuscitative efforts.

**Equipment and procedure.**

A variety of manufacturers supply capnometry equipment. Most capnometers use infrared absorption spectroscopy to measure $CO_2$ . Operation of each monitor and recorder should follow its manufacturer's instructions. Calibration of the monitor should be performed periodically with a known $CO_2$ source.

A sampling port slips between the endotracheal tube and a resuscitation bag. Some devices provide in-line continuous $CO_2$ readings, whereas others suction off samples of air from the endotracheal tube to a sensor in the body of the machine. Some capnometers are portable and battery-operated so that they may easily be used by prehospital care providers. [58] The clinician is interested in the end-tidal $CO_2$ (or peak) level, since this most closely approximates the alveolar $CO_2$ concentration.

Many manufacturers produce a multitude of capnometers for clinical use; many of these products are compared elsewhere. [59] Some capnometers are primarily designed for operating room or critical care unit use. Some systems incorporate 2 or 3 measurements, such as pulse oximetry and respiratory rate, along with capnometry.

However, pulse oximetry is not useful for patients in full cardiac arrest.

Two devices that seem appropriate for emergency department use are the Novametrix 1265 Capnogard and the Nellcor N-60 Stat Cap $CO_2$ Detector. The Novametrix 1265 Capnogard (Novametrix Medical Systems, Inc., Wallingford, Conn) weighs only 3.6 kg and is portable, with a 2-hour battery life (Fig. 16-7) (Figure Not Available) . It has a solid-state mainstream sensor and automatically adjusts to atmospheric pressure. The Nellcor N-60 Stat Cap $CO_2$ Detector (Nellcor, Inc., Hayward, Calif) weighs <1 kg and has a 16-hour battery life. It uses a mainstream sensor and requires no user calibration. Its portability makes it particularly useful for out-of-hospital cardiac arrest. Note that qualitative $CO_2$ detector devices are not recommended for assessing perfusion during CPR.

### Interpretation.

End-tidal $CO_2$ measurements are given either as a concentration in percent $CO_2$ (%$ET_{CO2}$ ) or as the partial pressure of $CO_2$ in mm Hg ($Pet_{CO2}$ ). Measurement of the $Pet_{CO2}$ varies slightly with the altitude at which the reading is taken. Animal studies have indicated that sequential end-tidal $CO_2$ measurements correlate with cardiac output, [57] myocardial perfusion pressure, [56] [60] and resuscitation from cardiac arrest. [60] [61]

Clinical studies assessing end-tidal $CO_2$ during CPR have been limited. In one series of 18 adults in late cardiac arrest, a %$ET_{CO2}$ of 1.7 to 1.8% was associated with a mean arterial

**Figure 16-7** (Figure Not Available) One commercial combination capnometer and pulse oximeter (Novametrix 1265 Capnogard). The mainstream sensor fits between the endotracheal tube and ventilation bag. Readouts of continuous $Pet_{CO2}$ readings permit the clinician to follow trends in $Pet_{CO2}$ levels and waveform analysis over time. *(Courtesy of Novametrix Medical Systems, Inc, Wallingford, Conn.)*

diastolic pressure of 22 to 25 mm Hg, and no patient was resuscitated. [60] Another study of 23 cardiac arrest victims, including 10 patients who attained spontaneous circulation, did not find a difference in %$ET_{CO2}$ between those resuscitated and those without return of spontaneous circulation. [56] Falk and associates also found no significant differences in the %$ET_{CO2}$ for resuscitated and nonresuscitated patients during CPR, although sequential changes in %$ET_{CO2}$ were seen with the onset of CPR and with return of spontaneous circulation. [57] However, Asplin and White found 1- and 2-minute $Pet_{CO2}$ levels monitored during out-of-hospital CPR to be higher in patients who had a return of spontaneous circulation. [58]

Several clinical studies have addressed differences in end-tidal $CO_2$ during ongoing CPR as a predictor of effectiveness of resuscitation. Callaham and Barton correlated initial end-tidal $CO_2$ with the return of a palpable pulse in 55 emergency department patients. The 14 patients who had a return of palpable pulse had a mean $Pet_{CO2}$ of 19 mm Hg, compared with 5 mm Hg for the 41 patients who did not develop pulses. [62] Another clinical study of 35 adult cardiac arrests found that the 9 patients who were successfully resuscitated also had a higher average $Pet_{CO2}$ during CPR than those who

could not be resuscitated (15 ± 4 vs 7 ± 5 mm Hg). [63] All 9 resuscitated patients had an average $Pet_{CO2}$ of 10 mm Hg or greater, and the 3 who survived to hospital discharge had an average $Pet_{CO2}$ of 17 mm Hg. One out-of-hospital cardiac arrest study found no survivors with a $Pet_{CO2}$ of 10 mm Hg after 20 minutes of arrest. [64]

Caution must be used in interpreting end-tidal $CO_2$ values. Experimentally, administration of sodium bicarbonate has been shown to increase excretion of $CO_2$ and hence adversely affect the correlation of end-tidal $CO_2$ with perfusion during CPR. Therefore, end-tidal $CO_2$ readings are not reflective of perfusion pressures during CPR for 5 minutes following the administration of bicarbonate. In addition, alterations in ventilations during CPR may affect end-tidal $CO_2$ readings. The effect of pressor agents during ongoing

CPR on end-tidal $CO_2$ is variable. [65] Experimentally, high doses of epinephrine lower end-tidal $CO_2$ and cardiac output during cardiac arrest while increasing myocardial perfusion pressures and coronary blood flow. [66] [67]

While explicit recommendations for use of capnometry to monitor patients during cardiac arrest are not warranted by the data available, the published data can be extrapolated to generate qualitative guidelines. If the $Pet_{CO2}$ value is 0, the ventilation system must be immediately reassessed. The endotracheal tube may have slipped into the esophagus, with resultant loss of ventilation. If tube placement cannot be ensured, the patient should be immediately reintubated. In a few cases, $Pet_{CO2}$ values of 0 may be due to cardiac arrest caused by a large pulmonary embolus obstructing pulmonary blood flow, with a resultant loss of $CO_2$ excretion. Finally, one must reevaluate the capnometer and ensure that it is working appropriately. The windows of the sensor cell may become clogged with mucus or blood, or the calibration may be inappropriate.

If the $Pet_{CO2}$ values are <10 mm Hg but not 0, one must reevaluate the artificial perfusion technique used during CPR. Readings below 10 mm Hg are associated with poor cardiac output during CPR and a poor prognosis for resuscitation. The force applied, the site of chest compression, and the rate of compressions should be assessed. A second rescuer or mechanical compressor may be needed.

If the $Pet_{CO2}$ values are >10 mm Hg, the resuscitators should try to optimize the $Pet_{CO2}$ values. Often the person doing chest compressions can directly observe the $Pet_{CO2}$ values produced. Subtle modifications in CPR technique using this feedback may then be used to improve the $Pet_{CO2}$ values.

The trend in $Pet_{CO2}$ values is important when monitoring patients in cardiac arrest. Decreasing values may mean that the resuscitator is tiring and a new person should do chest compressions. A consistent downward trend in $Pet_{CO2}$ values is a poor prognostic sign. On the other hand, a sudden upward trend in end-tidal $CO_2$ values may indicate a return of spontaneous circulation even before a pulse is felt. Such patients should be carefully assessed for spontaneous pulses, especially when the cardiac arrest is due to "pulseless electrical activity."

**Conclusions.**

Capnometry has potential as a noninvasive barometer of artificial perfusion during cardiac arrest. In general, optimal end-tidal $CO_2$ values are associated with optimal pulmonary perfusion. Hence, optimizing end-tidal $CO_2$ may improve the chance for resuscitation from cardiac arrest.

## SUMMARY

We have presented overviews of a number of proposed modifications of standard CPR. Limited evidence supports further evaluation of these techniques. Regardless of the closed-chest CPR technique used, assessment of ongoing CPR efforts is desirable for rational management of patients in cardiac arrest. Hemodynamic monitoring, especially of the aortic diastolic pressure and aorta-to-right atrium perfusion gradient (CPP), currently represents the best indicator of adequate cardiac perfusion during ongoing CPR. However, in most clinical cardiac arrest settings, it is impractical to measure these hemodynamic parameters. Therefore, indirect indices of perfusion such as capnometry may be useful in the overall evaluation of patients in cardiac arrest.

# Chapter 17 - Resuscitative Thoracotomy

**Robert L. Bartlett**

"If the etiology of the patient's deterioration is hemorrhage, surgery should not await resuscitation but is an integral part of resuscitation, as only when bleeding is controlled can the circulating blood volume be restored adequately." [1] As a multidisciplinary specialist, the emergency physician at times finds it necessary to use procedures previously considered to be the province of the surgical specialties. The emergency thoracotomy is the most invasive and controversial of these procedures. "The days when an individual specialty could restrict the use of a technical skill are long gone. Pertinent to technical skills are appropriate training, skills maintenance, and judgment as to when to apply them or when to withhold them." [2] The reality of emergency care is that few of the 6900 registered hospitals in the United States are classified as level I trauma centers with in-house surgical coverage. But almost all hospitals provide 24-hour emergency physician coverage. When death is imminent, the most qualified physician available should perform the indicated procedures without hesitation.

Since the early 1970s, the development of sophisticated emergency medical systems using well-trained paramedics, advanced life support, and rapid transport have increased the number of patients arriving at the emergency department (ED) in various stages of shock. With increasing frequency, emergency physicians are being given the opportunity to resuscitate patients who previously would have died at the scene. For some, survival is possible if an aggressive approach using emergency thoracotomy is taken. Therefore, knowing who may respond to thoracotomy becomes an important issue.

This chapter discusses the factors that influence the outcome of an emergency thoracotomy and the pathophysiology, diagnosis, and treatment of the injuries that require such an invasive procedure. The heart, lungs, and great vessels are the three vital structures in which injuries may require the use of a resuscitative thoracotomy. The mechanism of injury, prehospital vital signs, and systolic blood pressure following thoracotomy form the basic structure of a resuscitative algorithm.

Although this chapter provides considerable detail of the rationale for and the technique of resuscitative thoracotomy, the emergency physician should be aware of the *specific goals to be attained after opening the chest.* In the trauma patient receiving a resuscitative thoracotomy, the physician seeks to relieve any cardiac tamponade; to support cardiac function (with direct cardiac compression, cross-clamping of the aorta to improve coronary perfusion, and internal defibrillation when indicated); and to control hemorrhage from the heart, pulmonary vessels, thoracic wall, and great vessels. Although certain circumstances may require this sequence of resuscitation to be altered, the emergency physician should be cognizant of these goals on opening the chest.

Additionally, each institution should establish guidelines for the initiation of resuscitative thoracotomy and subsequent patient care in the ED. Ideally a preestablished plan of chest wound management and post-thoracotomy care should be established with the

service that will provide the emergency physician's surgical backup for those times when members of the surgical team cannot be on site at the time of the resuscitation. With such a plan, a team approach to resuscitation and optimal patient care is possible.

# INDICATIONS AND CONTRAINDICATIONS

## Penetrating Chest Injuries (General)

With penetrating thoracic trauma, the frequency of organ injury corresponds to the relative exposure of each organ. The lung is the most commonly injured organ, followed by the heart, the great vessels, the tracheobronchial tree, and the esophagus. Approximately 80% of penetrating chest injuries can be managed conservatively with tube thoracostomy if the only significant injury is a pneumothorax (see Chapter 9) .

The out-of-hospital mortality for penetrating chest wounds depends on the structures involved. For heart wounds in particular, the prehospital mortality is approximately 80%. Nonetheless, if any signs of life are present during the prehospital phase, these patients are *potentially* salvageable. The vital importance of speed and the use of the ED as the site for thoracotomy has been emphasized. [3] MacDonald and McDowell, commenting on their series of 28 emergency thoracotomies in a community hospital, observed that "resuscitation can be hampered by significant delays in assembling the necessary operating room staff. These delays sometimes mean that a trauma patient will be detained for a significant amount of time in the ED before a definitive procedure can be performed in the operating room." [4] "Delay and observation in the shocked, bleeding, or tamponading injury can only lead to prolongation of hypotension, acidosis, excessive requirement of blood and crystalloids, and on occasion sudden ventricular fibrillation or standstill." [5]

When the patient's vital signs suggest that cardiac arrest is imminent despite airway control and the initiation of volume replacement, a thoracotomy should be performed immediately. Death may result if the physician allows a cardiac arrest to occur while waiting for a possible response to ancillary therapy or while transporting the patient to the operating table. Beall and coworkers compared the mortality figures for emergency thoracotomies performed for penetrating cardiac injuries in patients with in-hospital cardiac arrest. [6] For the group receiving thoracotomies before cardiopulmonary arrest, the mortality was 15%. If the thoracotomy was performed after cardiopulmonary arrest, the mortality increased to 60%. The hardest part of any action is the decision to commence. It should be clear that every effort, including thoracotomy, should be made to avert, rather than treat, a cardiac arrest.

For patients in cardiac arrest, tracheal intubation and duration of out-of-hospital cardiopulmonary resuscitation (CPR) are prognostic factors that govern who will benefit from thoracotomy. Recent observations suggest that a time of 5 minutes of out-of-hospital CPR approaches the limits of viability of *nonintubated* trauma patients. The value of field

intubation is dramatic; the average time of CPR tolerated by intubated survivors is

double that of nonintubated survivors (9.4 vs 4.2 minutes). [7]

The type of electrical activity associated with the arrest forms a second tier of criteria. Although there are anecdotal responses to asystolic arrest with brief periods of resuscitation, these are extremely rare, and the presence of asystole should be considered a relative contraindication from a cost-benefit perspective. The presence of an agonal wide-complex idioventricular rhythm less than 40 beats/min and unresponsive to drug therapy also carries a grave prognosis. Ventricular fibrillation does not always indicate end-stage myocardial death and may be associated with a more favorable outcome to thoracotomy. [8] Finally, any patient with an organized rhythm faster than 40 beats/min is an *excellent* candidate for thoracotomy.

When the neurologic outcome of resuscitative thoracotomy is considered, a third decision factor is the presence of some form of neurologic activity, such as movement to painful stimuli or reactive pupils, during either the out-of-hospital phase or on arrival to the hospital. Patients with such recent neurologic activity are significantly more likely to survive without neurologic impairment. Although the absence of neurologic activity during the out-of-hospital phase may be associated with survival, in at least 1 series, all patients who left the hospital neurologically intact had some spontaneous movement present at some time in the field or ED. Of the 4 patients who survived in a persistent vegetative state, 3 had no evidence of movement (cerebral function) during their course in the field and in the ED. [9]

**Cardiac Injuries**

Eighty to 90% of stab wounds to the heart result in tamponade. The development of tamponade may be temporizing during the out-of-hospital phase. If tamponade does not occur, most patients with myocardial stab wounds will exsanguinate. [10] In contrast, when gunshot wounds involve the heart, the associated blast effect usually results in exsanguination rather than tamponade. [11]

Two additional factors that influence the development of tamponade are wound size and chamber involvement. Wounds of the myocardium less than 1 cm may spontaneously seal, depending on the location. Wounds larger than 1 cm usually continue to bleed regardless of the chamber involved. The low-pressure atrial wound usually forms a thrombus before tamponade develops. However, a wound of the higher-pressure right ventricle is often associated with tamponade. The thicker-walled left ventricle may spontaneously seal stab wounds up to 1 cm in length.

Cardiac tamponade is the *decompensated* phase of cardiac function resulting from increased intrapericardial pressure (see also Chapter 15) . Although one may suspect tamponade based on well-described signs, the clinical diagnosis of pericardial tamponade in the unstable trauma patient is notoriously difficult because of the combined effect of hemorrhagic and cardiogenic shock. The classic signs of Beck's triad (distended neck veins, hypotension, and decreased heart sounds) have *limited diagnostic value* for acute penetrating cardiac trauma. [12] Additional signs of tamponade include tachycardia; pulsus paradoxus; elevated central venous pressure; agitation and

confusion (reflecting decreased cerebral perfusion); air hunger; and cold, clammy skin.

Three mechanisms may partially compensate for the cardiac tamponade state. The first is reactive tachycardia. Reactive tachycardia during the hypotensive phase of tamponade is the usual finding, but for some patients, relative or absolute bradycardia may be present. [13] A second compensatory mechanism is the elevation of central venous pressure (CVP). However, many affected patients have marked volume depletion, and the CVP will not be elevated despite advanced tamponade. If hypotension persists and the CVP rises, the patient should be presumed to have cardiac tamponade; however, there may be a poor correlation between CVP and the extent of tamponade, even when the blood volume has been corrected. [14]

The third compensatory mechanism is increased peripheral vascular resistance that preserves arterial pressure in the presence of falling cardiac output. When hypotension does appear, it is an ominous sign, and the emergency physician must respond quickly.

**Pulmonary Injuries**

Pulmonary injuries can be divided into three types: parenchymal, tracheobronchial, and large-vessel. Parenchymal and tracheobronchial injuries rarely create a situation requiring thoracotomy in the ED, and most of these injuries are either rapidly fatal or can be adequately treated initially by tube thoracostomy.

Tracheobronchial injuries may be incurred from penetrating trauma. Although these injuries are more common with blunt trauma, most patients with this injury die at the scene. [15] With this injury, the airway is usually maintained, even in the presence of a complete transection. The stiff tracheobronchial cartilage tends to hold the lumen open while the peritracheal and peribronchial fasciae preserve the relationship of proximal to distal bronchi. Ninety percent of tracheobronchial tears occur within 3 cm of the carina. [16]

These tears most commonly involve the main stem bronchi. Less frequently, vertical tears may occur along the membranous cartilage line of the trachea. Complete division of the trachea is extremely rare. Depending on the size and location of the injury, patients may present with one or more of the following: massive hemoptysis when bronchial vessels are involved, airway obstruction, and pneumomediastinum or pneumothorax, with or without tension. If hemorrhaging is profuse or if the site of injury can be determined, the use of a bifid endotracheal tube or the unilateral intubation of a main stem bronchus will secure the airway.

Lacerations of the parenchyma unaccompanied by major vessel injuries generally respond to a tube thoracostomy. Although the associated hemothorax may be significant, reexpansion of the lung often halts or reduces bleeding. Reduction of parenchymal bleeding by negative pressure coaptation of the pleural surfaces is successful in 72 to 98% of cases. [5] If the initial chest tube drainage is more than 800 mL, with continued drainage at a rate of 50 mL every 10 minutes, or if there is persistent hypotension, immediate thoracotomy should be considered. Such patients rarely have simple parenchymal injuries; major vascular structures are usually involved. A

complication of parenchymal injuries that requires immediate thoracotomy is the development of air embolism.

## Air Embolism

### Presentation

Suspicion of air embolism following trauma is considered to be an indication for emergency thoracotomy. Until recently, the occurrence of air embolism following penetrating injuries of the lung had not been widely recognized, although it may be a significant cause of morbidity and mortality. [17]

The preoperative and postmortem diagnosis of air embolism is difficult. Air embolism is confirmed at thoracotomy by needle aspiration of a foamy air-blood admixture from the left or right ventricle or by visualization of air within the coronary arteries. Preoperative demonstration of air by aspiration from a central venous catheter or the femoral artery is rare, but it has been reported. [18]

Air embolism may appear in either the right or the left side of the circulatory system. Involvement of the right side of the circulation is referred to as *venous* or *pulmonary* air embolism. Generally, venous air is well tolerated, but death may occur when the volume of air reaches 5 to 8 mL/kg. The rate at which air moves into the circulation and the body's position are important determinants of the volume that can be tolerated. Death usually results from obstruction of the right ventricle or the pulmonary circulation. If the mean pulmonary arterial pressure exceeds 22 mm Hg, air may pass into the systemic circulation. Paradoxical air embolism may also occur in the 15 to 25% of patients who have a potentially patent foramen ovale.

The most common cause of venous air embolism is management error with IV therapy. Air embolism fatalities have been reported with subclavian venipuncture. [19] A pressure difference of 5 cm $H_2O$ across a 14-ga needle will allow the introduction of 100 mL of air per second. Injuries of the vena cava or the right ventricle also create obvious portals of entry into the right circulatory system.

Air embolism involving the left side of the circulatory system is referred to as *arterial* or *systemic* air embolism. The lethal volume depends on the organs to which it is distributed. As little as 0.5 mL of air in the left anterior descending coronary artery has led to ventricular fibrillation. Arterial air traverses systemic capillaries more readily than those in the pulmonary system. [20] Clinical manifestations of arterial air embolism are related to the involvement of the coronary or cerebral circulation. The distribution of arterial air is partly a function of body position.

Systemic air embolism following injury of the lung has only recently been described. The formation of traumatic bronchovenous fistulas creates potential entry points for air to move into the left side of the circulatory system. The only requirement is the formation of an air-blood gradient conducive to the inward movement of air. Although a lowered intravascular pressure from hemorrhage is a risk factor, the most important element in

all reports of air embolism has been the use of positive-pressure ventilation. [21]

In a review of 447 cases of major thoracic trauma, Yee and colleagues found adequate chart data to diagnose air embolism in 61 patients. [17] This incidence of 14% is remarkable in light of the small number of reported cases before 1973. [20] A mechanism of blunt injury should not preclude a consideration of this diagnosis, because 25% of patients with air embolism reported by Yee and coworkers had blunt trauma with associated lung injury secondary to multiple rib fractures or hilar disruption. The overall mortality was 56% (34 of 61 patients). Refractory cardiac arrest accounted for 63% of the operative deaths, with exsanguination or severe brain trauma as the cause in the remaining 37%.

The diagnosis of air embolism is easily overlooked because of the similarity of the signs and symptoms to those of hypovolemic shock. Two valuable signs that were present in 36% of patients were hemoptysis and the occurrence of cardiac arrest *after* intubation and ventilation. The diagnosis of air embolism also should be considered when unconsciousness develops suddenly and is followed by seizures in a patient with lung injury on positive-pressure ventilation. [22]

**Management**

A high index of suspicion with rapid control of the source of air embolism is vital. The patient should immediately be placed in the Trendelenburg (head-down) position to minimize cerebral involvement by directing the air emboli to less critical organs. This step should be followed by a left anterolateral thoracotomy. The exposed thorax should be flooded with sterile saline. Peripheral bronchovenous fistulas can be identified by the bloody froth created during positive-pressure ventilation. A quick search for hilar injuries should be carried out in the patient with blunt trauma. If the source of air embolism is not readily apparent, a contralateral thoracotomy should be performed. Once the bronchovenous communication is controlled, needle aspiration of the residual air that commonly remains in the left ventricle and the aorta should be performed. If the patient is hypotensive, the aorta may now be cross-clamped or compressed with the hand. "Reflex" cross-clamping of the aorta before control of bronchovenous fistulas and removal of residual air will result in further dissemination of air to the heart and the brain.

**Adjunctive Therapy**

As mentioned earlier, air emboli traverse capillary beds if the blood pressure is high enough. After control of the bronchovenous fistula, a brief period of proximal aortic hypertension can be produced by cross-clamping of the descending aorta. Systemic arterial pressure should be maintained with adequate fluid resuscitation. If vasopressors are required, metaraminol (Aramine) appears to be the drug of choice. Other pressor agents such as dopamine, epinephrine, or norepinephrine increase systemic pressure but do not necessarily facilitate the left-to-right passage of bubbles as well as metaraminol does. [23]

Left atrial pressure should be maintained at a high level. The ventilator inspiratory

pressures should be kept as low as possible, and 100% oxygen should be used to facilitate diffusion of nitrogen from emboli. Pharmacotherapy may include steroids, mannitol, aspirin, and barbiturates in conjunction with hypothermia. The most important adjunctive therapy is the use of a hyperbaric chamber.

Hyperbaric oxygen therapy is beneficial because it (1) compresses air bubbles; (2) establishes a high diffusion gradient, which greatly speeds the dissolution of the bubbles; (3) improves the oxygenation of ischemic tissues and lowers intracranial pressure; and (4) reduces the reperfusion injury that invariably follows the passage of bubbles. When it is available and logistically practical, hyperbaric oxygen therapy should be considered, *even though it may be many hours before it can be initiated*. The effectiveness of hyperbaric oxygen therapy is illustrated by cases of success and improvement

even when as many as 36 hours elapsed before pressurization. [24]

## Major Vascular Injuries

Major vascular injury resulting in rapid deterioration following blunt or penetrating trauma requires the use of an emergency thoracotomy for diagnosis, resuscitation, and control of hemorrhage. Mavroudis and others reviewed 76 patients with thoracic vascular injury from mixed trauma who received an ED thoracotomy because they were moribund or an immediate thoracotomy in the operating suite for hemodynamic instability. The three most common sites of vascular injury are the pulmonary artery (28% of cases), intercostal artery (23% of cases), and pulmonary vein (20% of cases). Aortic injuries account for only 12% of the injuries requiring immediate surgical intervention. However, even with immediate intervention, survival rates are low (14 to 29%). Air embolism was the cause of death in 18% of cases. [25]

The clinical approach to patients with suspected major vascular injury depends on hemodynamic status, the mechanism of injury, and the presence of associated injuries. If the patient's condition is sufficiently stable, angiography is a valuable diagnostic measure, although the risk of sudden deterioration necessitates constant monitoring. If the patient's condition is deteriorating rapidly and vascular injury is suspected, emergency thoracotomy plays a dual role as a diagnostic and a resuscitative procedure. It must be emphasized that patients with seemingly trivial penetrating wounds may appear stable and yet may precipitously exsanguinate and suffer an unexpected arrest.

## Blunt Trauma and Penetrating Abdominal Injury

Emergency resuscitative thoracotomy for *blunt* trauma has limited ability to resuscitate patients who arrive with agonal signs. [26] *Therefore, this procedure is relatively contraindicated for the management of blunt trauma in both adult and pediatric populations*. [27] The exception to this rule is the blunt trauma patient who arrives in the ED with a measurable blood pressure, but whose condition deteriorates precipitously, leading to suspicion of an intrathoracic injury. [28]

In the setting of penetrating abdominal injury, thoracotomy with cross-clamping of the thoracic aorta to control hemorrhage from the injury has been advocated, but survival rates have been poor for those undergoing this procedure, and its routine use is not supported. The collective survival rate for 194 cases described in the literature is only 5%. [29] Three factors contribute to this low figure. First, aortic occlusion does not substantially affect the rate and volume of bleeding from major venous injuries. Second, all vital signs had been lost in most patients by the time of thoracotomy. Third, multiple collateral pathways around the cross-clamped aorta diminish the effectiveness of this procedure. [30]

Aortic cross-clamping for massive hemoperitoneum was originally conceived as a preoperative "prophylactic" procedure to prevent sudden hypotension following abdominal decompression. Applied in the operating room in this role, it is of clear benefit when systolic pressure cannot be raised above 80 mm Hg prior to laparotomy. [31]

## Open-Chest Resuscitation for Nontraumatic Arrest

Failure to resuscitate patients from cardiac arrest is a result of (1) a delay in the onset of CPR, (2) the use of less than optimal resuscitative techniques, or (3) the intractability of the underlying disease process. The development of closed-chest resuscitation, which is quickly and easily applied, coupled with the development of more advanced out-of-hospital care has dramatically reduced the number of failures caused by a delay in the onset of CPR. Techniques to improve closed-chest resuscitation continue to be sought (see Chapter 16 , because after the first 5 minutes of CPR in adults, closed-chest compression may provide inadequate cerebral blood flow and little myocardial perfusion. [32]

The mean coronary perfusion pressure with conventional CPR is approximately 7 mm Hg, whereas open-chest cardiac massage produces a coronary perfusion pressure of 32 mm Hg. [33] The cardiac index with conventional CPR is 0.6 L/min/m [2] , and with direct cardiac massage the index is doubled. [34] Similarly, cortical blood flow cannot be maintained at more than 10% of normal during conventional CPR. [35] [36]

At present, the precise role of open-chest resuscitation for nontraumatic arrests is poorly defined, and the procedure is not considered a standard of care. Although several indications have been suggested, only 2 theoretically can be readily accepted. The first indication is for resuscitation of patients with hypothermic arrest (see Chapter 71) . Certainly, in this setting, cardiopulmonary bypass is the most rapid method of core rewarming, but it is rarely available on an immediate basis, or bypass is relatively contraindicated because anticoagulation would be used in the setting of known or suspected trauma. Open thoracotomy with mediastinal irrigation has been used successfully for severe hypothermia with cardiac arrest. With severe hypothermia, ventricular fibrillation is resistant to chemical or electrical conversion, and prolonged periods of closed-chest compression must be provided during the long process of rewarming.

Patients surviving neurologically intact in previously published case reports of

open-chest resuscitation with direct cardiac rewarming had 30 to 180 minutes of internal massage. [37] Core rewarming with this technique can be as fast as 8 °C/hour, and it preferentially rewarms the heart and lungs first. Such a rewarming sequence prevents "rewarming shock," which may occur if the extremities or abdomen rewarm first, producing metabolic and circulatory demands that exceed the capacity of the heart. Tap water at a temperature of 40 °C can be poured slowly over the heart and into the thorax. Sterile saline heated in a microwave oven to the same temperature is equally effective and somewhat more hygienic. Performing a thoracotomy for hypothermic arrest does not preclude the subsequent use of cardiac bypass. If there are no major contraindications to bypass, such as head trauma, open-chest resuscitation with mediastinal rewarming can be performed while arrangements for cardiac bypass are made.

The second more provocative theoretical indication is for use in normothermic arrests. Long-term survival is rare when the duration of closed-chest resuscitation is *continuous* for more than 30 minutes without cardiac response. The probability of long-term survival for witnessed medical arrests is approximately 86% during the first 10 minutes of

resuscitation. [38] This is reduced to 30% by 16 minutes and becomes less than 1% after 30 minutes. [39] [40] This temporal survival profile is predicated on basic life support beginning within 4 minutes and advanced life support being initiated within 8 minutes of cardiac arrest.

Investigation by Kern attempted to address the optimum timing of open-chest cardiac massage following closed-chest compression using a canine model. [41] It appears that if initiation of open-chest cardiac massage is delayed for more than 20 minutes from the onset of cardiac arrest, few or no successful outcomes can be expected despite the prompt prior institution of closed-chest compression. However, beginning direct cardiac massage after 15 minutes of closed-chest massage could still produce a 75% success rate vs a 12% success rate in the control group in which 15 minutes of closed-chest compression was not followed by direct cardiac massage.

In a comparative study of closed- and open-chest resuscitation using a canine model, Bartlett and coworkers demonstrated improved survival and neurologic outcome with the open-chest cardiac compression method. Only 10% of the control animals could be resuscitated after 50 minutes of closed-chest resuscitation, and all had fixed and dilated pupils. An experimental group received 10 minutes of closed-chest resuscitation followed by 40 minutes of open-chest resuscitation for a total arrest time of 50 minutes. *All* of these dogs were resuscitated; equally important was the preservation of the pupillary light reflex in 90% of these animals. [42] These animal studies should be considered "best case" scenarios in that the animals did not have underlying cardiac or neurologic disease, and closed-chest CPR was promptly instituted.

Based on these studies, the "best case" temporal window of efficacy for open-chest resuscitation is within 10 and 15 minutes of arrest and assumes performance of prior closed-chest CPR. For the vast majority of sudden death victims, it is unlikely that they will be at a facility with open thoracotomy capability within that time frame. Clinical studies comparing open- and closed-chest resuscitation suggest that the clinical utility of

open-chest resuscitation for out-of-hospital arrests may be extremely limited despite the impressive cardiac outputs that can be generated.

## EQUIPMENT

The physician must carefully consider the instruments to be included in a resuscitation thoracotomy tray. The inclusion of too many instruments makes the tray cumbersome and delays the procedure. Nonessential instruments are best kept available in the resuscitation room in case they are needed for specific repair (e.g., Foley catheter for stellate wound tamponade).

The following items are essential for a thoracotomy tray:

> Scalpel with attached No. 20 blade
>
> Mayo scissors (or long Metzenbaum scissors)
>
> Rib spreaders
>
> Liebsche knife (or sternal osteotome with hammer)
>
> 2 tissue forceps (10 in.)
>
> 2 Satinsky vascular clamps
>
> 3 Hegar needle holders (10 in.)
>
> 2-0 or larger silk sutures on large-curve needle
>
> Teflon patches
>
> Suture scissors
>
> Aortic tamponade instrument
>
> Skin stapler (6 mm staples)

The following items are optional for the tray and can be supplied as needed by an assistant:

> 6 towel clips
>
> 4 to 6 hemostats (curved and straight)

Metzenbaum scissors

Right-angled clamp

Foley catheter (20 Fr, 30-mL balloon)--sterile saline/ syringe

Chest tube (No. 30, Argyle)

12 lap sponges or gauze pads

6 towels

In addition, functioning suction and sterile suction tips, antiseptic solution, sterile gloves, a defibrillator with internal paddles, and overhead surgical lights are needed in the resuscitation room. In the unlikely event that the patient awakens during the procedure, sedative and analgesic agents should be available for sedation, amnesia, and pain control.

## PROCEDURE

### Preliminary Considerations

In the urban out-of-hospital setting in which a trauma center is less than 15 minutes away, patients with penetrating thoracic injuries should receive immediate transportation with the least possible field time. Two studies suggest that this "scoop-and-run" approach provides a better survival rate. [45] [46]

For all trauma victims presenting to the ED with hypotension, the initial working diagnosis must be one of volume depletion. Other possibilities should be rapidly excluded, such as tension pneumothorax, cardiac tamponade, air embolism, and neurogenic or cardiogenic shock. A useful algorithmic overview of the approach to chest trauma is shown in Figure 17-1 .

Because a large amount of blood may be lost into the chest, an autotransfusion system should be available (see Chapter 28) . The use of autotransfusion has several benefits. [47] The most important advantages are (1) immediate availability of compatible, warm blood; (2) significantly higher levels of 2,3-diphosphoglycerate (DPG) than in stored blood; (3) elimination of transfusion diseases; and (4) less risk of exhausting the banked supply of the patient's blood type. The fourth point can be crucial when there are blood bank shortages or crossmatch problems.

**Airway Control During Thoracotomy**

Patients undergoing resuscitative thoracotomy in the ED obviously require assisted ventilation. Airway control is best obtained with standard orotracheal intubation, but exposure of the thoracic organs and surgical repairs or procedures may be hampered by frequent inflations of the left lung. Selective one-lung ventilation using a specialized double-lumen endotracheal tube is an established technique in thoracic surgery, but the availability of and experience with these devices is limited. The right lung often can be selectively intubated by blindly advancing a standard single-lumen endotracheal tube to a depth of 30 cm (measured at the corner of the mouth) in adult patients. [48] Although the left lung and the right upper lobe are not ventilated with the

**Figure 17-1** An algorithmic approach to chest trauma. QRS, organized electrical activity; VFib, ventricular fibrillation; (+)TAP, pericardial tap yielding blood.

tracheal tube in this position, animal studies and preliminary data from humans suggest that selective right lung ventilation provides adequate oxygenation and ventilation for at least 60 minutes, thereby expediting the thoracotomy by minimizing the technical problems encountered by continual left lung inflation. [48]

**Anesthesia and Amnesia**

Comatose patients undergoing resuscitation may regain consciousness during a successful emergency thoracotomy, but the use of paralyzing agents may mask the return of awareness. The physician must be cognizant of this phenomenon and administer adequate analgesia and amnestic agents to the paralyzed and ventilated patient. Due to the profound shock that accompanies this procedure, ketamine (2 mg/kg IV) and midazolam (0.10 to 0.2 mg/kg IV) have been recommended. [49] It would be prudent to administer these agents routinely if the paralyzed patient demonstrates viable perfusion during resuscitation.

**Subxiphoid Pericardial Window**

Most patients who demonstrate viable perfusion with a suspected cardiac injury are candidates for a subxiphoid pericardial window for diagnosis and decompression of a suspected evolving pericardial fluid collection (see also Chapter 15) . This procedure is best performed in the operating suite.

**Anterolateral Thoracotomy Incision**

The patient should be intubated. A nasogastric tube can be passed to help differentiate the esophagus from the aorta (Fig. 17-2 *A*). When the site of injury is unknown and the patient's status requires immediate intervention for possible intrathoracic injuries, a left anterolateral incision over the fifth rib with dissection into the fourth intercostal space provides the best access to the heart and the great vessels. In the setting of cardiac arrest, time should not be taken to count the rib spaces. An incision just beneath the nipple in the male or along the inframammary fold in the female will approximate the

fourth intercostal space (Fig. 17-2 *B* and *C*). Closed-chest compressions are continued during the initial incision. The first sweep of the scalpel (No. 20 blade) should separate skin, subcutaneous fat, and the superficial portions of the pectoralis and serratus muscles. It is important to establish wide exposure from the outset by extending the skin incision past the posterior axillary line. To facilitate this

**Figure 17-2** Left anterolateral thoracotomy. *A,* Several towels or sandbags are placed under the left scapula and the arm is raised above the head. The patient should be intubated. A nasogastric tube can be inserted to facilitate differentiation of the esophagus from the aorta. *B,* The left anterolateral submammary incision is the suggested initial approach. Ideally the incision is made between the fourth and fifth ribs. Generally the incision is just inferior to the nipple (male) or along the inframammary fold (female). The incision begins on the sternum and extends to the posterior axillary line, where it should be deep enough to partially transect the latissimus dorsi muscle. *C, Dashes* indicate the incision site of the inframammary fold in women.

action, quickly wedge towels or sheets under the left posterior chest and place the patient's left arm above the head (see Fig. 17-2 *A*). Inadequate exposure, rib fractures, and additional delays occur when the skin incision is too limited.

To enter the pleural space, a small incision is made in the intercostal muscles and one blade of the scissors is inserted. The intercostal muscles are then cut with the scissors to expose the thoracic cavity (Fig. 17-3 *A*). When dividing the intercostal muscles with a scalpel or Mayo or Metzenbaum scissors, be careful not to lacerate the lung. With the first opening of the pleura, ventilations should be stopped momentarily. This will allow the lung to collapse away from the chest wall. The intercostal incision is placed just over the top of the fifth rib so as to avoid the intercostal artery. Some surgeons prefer to begin the thoracotomy incision over the sternum, whereas others begin 2 cm lateral to the edge of the sternum, hoping to avoid the internal mammary artery. Should the internal mammary artery be transected during the procedure, hemorrhage is generally minimal until after perfusion is reestablished. At that time, the patient can hemorrhage actively from a lacerated internal mammary artery. Therefore, all internal mammary artery lacerations should be ligated once perfusion is established.

The intercostal space is spread and a chest wall retractor (rib spreader) is placed with the handle and ratchet bar down (Fig. 17-3 *B*). If the retractor is placed with the handle up, the ratchet bar will prevent extension of the incision into the right chest. When the site of injury is to the right of the heart and cannot be reached, a transsternal extension into the right chest is performed with a Liebsche knife or a sternal osteotome. In patients with suspected left subclavian vessel injuries or aortic arch injuries, better exposure and control are obtained when the third intercostal space is used. If access is still difficult, the superior ribs may be separated at the costochondral junction. Ribs may be broken during spreading, so care must be taken to avoid being cut on the sharp bone edges. If a massive hemothorax is encountered, clots should be removed manually and towels used to soak up blood.

## Pericardiotomy

If cardiac arrest has occurred, the question of whether to open the pericardial sac arises. If the myocardium cannot be visualized, the pericardium should be opened. However, in some cases, the myocardium can be evaluated through the intact pericardium. Nonetheless, if there is no other obvious injury in the chest and a cardiac injury is possible, the pericardium should be opened routinely, because *it may be difficult to definitively rule out pericardial tamponade by visual inspection alone*. The author has had experience with two cases in which a substantial amount of clotted blood was hidden in the posterior, dependent aspect of the pericardium. The hemopericardium and associated injury were discovered during a continued search for possible injuries.

If the physician is confident that tamponade is not present, it is usually best to leave the pericardial sac closed while other life-threatening injuries are addressed. Opening the pericardium increases the risk of complications. For example, any delay in beginning cardiac compressions will add to the risk of cerebral damage. The myocardium or a coronary vessel may be injured. The left phrenic nerve may

**Figure 17-3** A, When entering the pleural cavity, it is important to make the incision on top of the rib to avoid the intercostal vessels. Once a hole has been made into the pleural space, the incision is widened with blunt scissors by cutting the intercostal muscles. The 4th and 5th fingers of the operator's free hand are inserted into the pleural space to fend off the lung as the scissors divide the intercostal muscle. Momentary cessation of ventilation will collapse the lung. Alternatively, the right mainstem bronchus can be intubated, which permits continuous ventilation and oxygenation without inflating the left lung into the operating field. *B,* The incision must always be carried to the posterior axillary line to maximize exposure. The rib spreader should be placed with the handle laterally. Because it can be difficult to determine if tamponade has occurred using visual inspection alone, the pericardium must be opened to definitively determine if tamponade is present. Using tissue pick ups with teeth, the operator must press hard against the pericardium to engage it within the tissue pick ups. The incision is started near the diaphragm and anterior to the phrenic nerve, which is easily identified as a thick tendon-like structure. Using blunt scissors, the incision is carried to the root of the aorta.

be cut by mistake, and if there has been previous pericardial disease, adhesions may be present. If attempts are made to separate these adhesions rapidly, tears of the atrial or right ventricular wall can occur. The incidence of traumatic rupture of the atria or the right ventricle during massage is greater when the pericardium is open. With an intact pericardium, pressure is distributed over a larger area and the pericardial fluid seldom allows the compressing fingers to remain in one spot for a prolonged period.

Patients with tamponade require pericardiotomy. This is performed in a location anterior and parallel to the left phrenic nerve. The incision should start near the diaphragm to avoid possible injury of the coronary arteries. The pericardial sac is lifted with forceps, and scissors are used to make a small hole in the sac; the scissors are then used to further open the anterior pericardium from the apex of the heart to the root of the aorta. When the pericardium is under tension, it may be difficult to grasp the pericardium with forceps. In that case, sharp, straight Mayo scissors are used to divide the pericardium

by layers. If the heart is in arrest, speed is important, and sharp scissors should be used to "catch" the pericardium and to start the pericardiotomy. To do this, the point of the scissors is held almost parallel to the surface of the heart with enough pressure to create a wrinkle in the pericardium that can be punctured as the scissors are moved forward. Moderate pressure must be used to puncture the fibrous pericardium. The sudden "give" that occurs when the pericardium opens may result in a laceration of the myocardium if the point of the scissors is unnecessarily angled toward the heart. Clots of blood are removed from the pericardial sac by the sweeping motion of a gloved hand or with sterile lap sponges or gauze pads.

## Direct Cardiac Compressions

Three techniques for cardiac compression have been advocated: one-handed compression, one-handed with sternal compression, and two-handed (bimanual) compression (Fig. 17-4) . The *one-handed compression* method is performed with the thumb placed over the left ventricle, the opposing fingers over the right ventricle, and the apex of the heart resting in the palm of the hand. The *one-handed with sternal compression* method also is performed with the fingers flat. The fingers of the hand are held tightly together to form a flat surface over the left ventricle while compressing the heart up against the sternum. To perform the *two-handed compression* method, the left hand is cupped and placed over the right ventricle. The fingers of the right hand are held tightly together to form a flat surface supporting the left ventricle. This flat surface compresses the heart against the cupped surface of

**Figure 17-4** Two-handed method of cardiac massage. The ventricles are compressed toward the interventricular septum. Note how the hands flank the left anterior descending artery, which overlies the septum. Avoid using excessive finger *tip* pressure or lifting the heart, which slows ventricular filling by distorting the soft atrial caval junction.

the left hand. Of these three, the bimanual technique is consistently superior, and whenever possible, it is the preferred method. [50]

A difference of opinion exists regarding the optimal rate at which the heart should be compressed. Most of the literature has recommended a rate of 50 to 60 compressions per minute; however, no physiologic data support such a recommendation. Johnson and Kirby studied the relationship of compression rate to cardiac output and blood pressure and found these parameters to be directly related. [51]

It is important to remember the following points while performing cardiac compression:

1. Finger *tip* pressure should be avoided at all times. Compression is performed using the entire palmar surface of the fingers.
2. Whichever technique is used, the force of compression should be perpendicular to the plane of the septum. The anterior descending coronary artery is located over the interventricular septum and is a helpful landmark to orient proper hand placement. It is clearly seen, with or without the pericardium open.
3. The fingers should be positioned so that the coronary arteries will not be occluded.

4. Venous filling of the heart is especially sensitive to changes in position. It is important to maintain a relatively normal anatomic position of the heart to *prevent* kinking of the vena cava and pulmonary veins. The heart should not be angled more than 30 degrees into the left chest.
5. It is also essential to completely relax the heart between compressions. If present, intra-arterial pressure monitoring is of tremendous value for assessing the consistency and effectiveness of compressions.

**Control of Hemorrhagic Cardiac Wounds**

One may partially control active bleeding from ventricular wounds by placing the finger of one hand over the wound while using the other hand to stabilize the beating heart. This maneuver buys time while the physician prepares to repair the injury. The use of surgical staples for ventricular wound closure is an extremely rapid method for controlling hemorrhage (Fig. 17-5) . [52] This technique may be particularly useful with large or multiple lacerations. Another advantage is that stapling does not expose the operator to the risk of a needle stick. Macho and coworkers reported a 93% success rate in temporarily controlling hemorrhage in 28 patients (33 lacerations) with penetrating injuries to both atria and ventricles using a standard skin stapler with wide (6 mm) staples placed at 5-mm intervals (Auto-Suture 35W, U.S. Surgical Corp, Norwalk, Conn). [53] The rotating long neck of the Ethicon Proximate Quantum Skin Stapler (Model PQW-35, Ethicon, Inc, Somerville, NJ) also is advantageous for obtaining proper orientation of the staples during placement. The staples may be left in place and reinforced or replaced on further wound exploration in the operating room.

Alternatively, the wound can be repaired by placement of several horizontal mattress sutures under the tamponading finger (Fig. 17-6) . Nonabsorbable 2-0 silk sutures are customarily used. Smaller sutures should *not* be used, and nylon sutures should be avoided. Some physicians prefer to use even larger silk sutures, such as No. 1 or 2 (note that this is *not the same as* 0 [1-0] or 0-0 [2-0] sutures). When multiple sutures are needed, they should all be in place before they are tied. This allows for a rapid and equal distribution of wound tension, which prevents tearing of the myocardium. [54] Passing the suture through Teflon pledgets also prevents the suture from cutting through the myocardium. It is especially important to use Teflon pledgets for reinforcement when the myocardium has been weakened by the blast effect of a bullet. [55]

With large wounds that cannot be palpably controlled, an incomplete horizontal mattress suture should be placed on either side of the wound (Fig. 17-7) . The free ends are then crossed to stop the bleeding. The actual reparative sutures can then be accurately placed. It must be stressed that suturing the myocardium requires good technique. Excessive tension may tear the myocardium and aggravate the situation. Keys to success include the use of an appropriate-sized suture, a generous "bite" with the needle, and the application of only enough tension necessary to control bleeding.

If exsanguinating hemorrhage is not controlled by the aforementioned methods, temporary inflow occlusion can be used. Inflow occlusion may be applied intermittently for 60 to 90 seconds. During occlusion the heart shrinks, hemorrhage is controlled, and

sutures can be placed in a decompressed injury. Two techniques that are useful are vascular clamping of the superior and inferior vena cava for partial inflow occlusion 56 and the Sauerbruch grip (Fig. 17-8) for occlusion of the vena cava between the ring and the middle finger of the left hand for partial inflow occlusion. [57] Use of the Sauerbruch grip has the utility of speed and the added advantage of cradling and stabilizing the heart during repair

**Figure 17-5** Technique of cardiac stapling to temporarily control hemorrhage. An assistant can approximate tissues with fingertip pressure or, as illustrated, 2 half-horizontal sutures can be used to approximate the wound edges and reduce bleeding. A skin stapler with wide (6 mm) staples is used to place staples 5 mm apart. This technique may be used for atrial and ventricular lacerations. Following stabilization of the patient's condition, the wound is revised in the operating room.

of wounds over either ventricle or the left atrium. The Sauerbruch grip will only interfere with the repair of wounds involving the right atrium.

Insertion of a Foley catheter (20 Fr with a 30-mL balloon) through a wound is another technique for temporarily controlling hemorrhage. [58] Following insertion of the catheter, the balloon is inflated, the catheter is clamped to prevent air embolism, and gentle traction is applied (Fig. 17-9) . Enough traction is applied to slow the bleeding to an acceptable level for visualization and repair. Attempts to achieve complete hemostasis with excessive traction may pull the catheter out and potentially enlarge the wound. The balloon will effectively occlude the wound internally. When repairing the wound, the operator must be careful with the suture needle to prevent rupturing the balloon. A pursestring suture is

**Figure 17-6** A, Technique of repair. Multiple horizontal mattress sutures are placed 6 mm from the wound edge before tying. The wound is closed just enough to stop the bleeding. Teflon pledgets are used for reinforcement. Closure without pledgets incurs the risk of sutures ripping through the contracting myocardium. Similarly, the use of simple vertical sutures should be discouraged because of the risk of suture dissection through the myocardium. *B,* For repairs near a coronary artery, care is taken to pass the suture under the artery.

commonly used. Temporarily pushing the balloon into the ventricular lumen during needle passage is important to prevent rupture. Alternatively, the balloon can be temporarily deflated during suture placement. It is important to use normal saline when inflating the balloon. Use of air will result in air embolism if the balloon is ruptured by the suture needle.

**Figure 17-7** Hemorrhage control using 2 widely placed incomplete mattress sutures. An assistant then crosses the two "half-horizontal" sutures to bring the wound edges into apposition. By controlling the hemorrhage in this manner, the assistant's hands are outside of the operative field, fully exposing the wound edges. This facilitates a more orderly closure of the wound. Following repair of the wound, the sutures may either be removed or tied to each other.

**Figure 17-8** Sauerbruch maneuver: the *method of choice* for reducing heavy bleeding from cardiac wounds. Venous inflow occlusion is achieved by using the first and second or second and third fingers as

a clamp.

Foley catheters have several advantages over other methods of controlling cardiac wounds. With the digital method, the fingertip will often slip if there is a strong heartbeat, the wound cannot be visualized during repair, and digital pressure significantly interferes with cardiac massage. Intermittent total venous inflow occlusion is an effective method of controlling bleeding and decompressing the heart, but such control will be at the expense of a poor cardiac output. Comparatively, the Foley catheter causes less cardiovascular interference, although inflation near the base of the ventricle may obstruct blood flow. Attempts to elevate the heart for control and repair of posterior cardiac wounds will often result in cardiac arrest by reduction of both venous and arterial flow. With posterior injuries, one cannot continuously view the wound for digital control of bleeding. Use of a catheter does not require continued viewing after initial placement. If bleeding can be controlled, repairs in this location should await full volume expansion or cardiopulmonary

**Figure 17-9** Serial illustration. Gentle traction on an inflated Foley catheter will control hemorrhage and allow easy repair. The balloon is inflated with saline, and care is taken to avoid rupturing the balloon with the suture needle. This technique is particularly useful with injuries of the inferior cavoatrial junction, with posterior wounds, and during cardiac massage. Volume loading can be obtained by infusion of blood or crystalloid solutions through the lumen of the catheter. Care should be taken to avoid an air embolus through the lumen of the catheter during placement.

**Figure 17-10** Technique for elective fibrillation: 20 J (watt-sec) is delivered through internal defibrillating paddles placed perpendicular to the epicardium. Coronary vessels should be avoided during paddle placement.

bypass. [59] Regardless of location, the most valuable feature of Foley catheter use is the ability to control hemorrhage without interfering with cardiac compression.

Deliberate *fibrillation* (to halt myocardial contractions) should be considered as a last resort for repair of difficult wounds of the ventricle or the proximal aorta. Elective cardiac arrest is best tolerated if there is adequate blood volume and oxygenation before fibrillation. To induce fibrillation, the internal cardiac paddles are placed perpendicular ("on-edge") to the surface of the heart and are discharged at 20 J (Fig. 17-10) . [56] This produces a local area of depolarization. The resulting disparity in relative refractory periods sets up a circus movement, which produces ventricular fibrillation. The heart should be massaged intermittently during repair, and the duration of fibrillation should not exceed 3 to 4 minutes.

*Defibrillation* is accomplished while the internal paddles are firmly pressed *tangentially* over the right and left ventricles. Following repair, the epicardium is often dry and should be moistened with saline to improve electrical conduction. An energy level of 20 J is used. If the initial attempt is unsuccessful, repeated shocks at the same setting should be used. Higher energy levels can cause myocardial necrosis. [60]

Defibrillation through an intact pericardium also should begin with 20 J. If unsuccessful,

the shock should be repeated once and then increased to between 40 to 60 J.

Management of the wounded heart that has spontaneously arrested is controversial. Some physicians have recommended a rapid repair of ventricular wounds while the heart is arrested. Others consider immediate cardiac massage and reversal of cardiac arrest to be more important. Immediate cardiac massage to maintain blood flow is probably the best approach. When cardiac arrest occurs, physiologic reserves have been depleted, and a delay for repair during arrest would only diminish the chance of a successful resuscitation.

Wounds of the atria are initially managed with partial occlusion clamps (Fig. 17-11) . Because of the thin structure and instability of the atrial wall, digital pressure will not effectively stop bleeding. Injuries near the caval-atrial junction are not amenable to clamping. In this location a Foley catheter should be used to tamponade the wound (Fig. 17-12) . [61] Care must be exercised to avoid obstruction of atrial filling with the inflated balloon. During wound closure, the catheter should be pushed away from the ventricular wall or the balloon temporarily deflated to avoid rupture of the balloon. Skin staples also have been used for closure of atrial wounds. [53]

Wounds of the septa, valves, and coronary arteries require definitive repair in the operating suite. Hemorrhage from a coronary artery can generally be controlled with digital pressure. Ligation of a coronary artery should be avoided when possible.

**Control of Hemorrhagic Great Vessel Wounds**

Wounds of the great vessels can be controlled with digital pressure or partial occlusion clamps. Exsanguinating hemorrhage

**Figure 17-11** Use of a partial occluding clamp in different locations for control of bleeding and subsequent repair.

**Figure 17-12** Wounds of the inferior cavoatrial junction are difficult to manage with simple vascular clamping. *A-D,* Use of a Foley catheter provides satisfactory control.

from the left subclavian artery can be prevented by cross-clamping of the intrathoracic portion of the artery. Cross-clamping of the right subclavian artery is very difficult. For injuries of this vessel, compression with laparotomy pads in the apex of the pleura from below, and the supraclavicular fossa from above (Fig. 17-13) , will prevent further bleeding as the patient is stabilized and moved to the operating suite. [52]

Large or difficult vena caval injuries may be controlled with a temporary intravascular shunt to maintain venous return while providing vascular isolation of the injured segment. [62] This is a difficult and time-consuming procedure that is best done in the

operating room, if the patient survives long enough.

Occasionally, fluid resuscitation can be accomplished by infusing fluid directly into the right atrium. The usual technique for placing atrial catheters using a pursestring suture in the right atrium has several disadvantages. First, it is relatively time-consuming for a patient in cardiac arrest, and cardiac massage is often interrupted to allow suture placement. In addition, the suture may tear the atrial appendage, the suture holes are frequently associated with fluid leaks through the thin atrial wall, and the catheter can slide out of place. Samuelson described an innovative technique utilizing an umbilical cord clamp with a center hole (Fig. 17-14 A). A standard umbilical cord clamp (Hollister, Inc., Libertyville, Ill) is modified by drilling a hole through the center to match the size of standard IV tubing or whatever catheter is to be used. [63] The diameter of the hole should hold the catheter firmly enough to prevent slippage. These clamps, by necessity, must be prepared in advance and gas sterilized.

To place a catheter using this technique, the right atrial

Figure 17-13 Cross-clamping for control of subclavian bleeding is difficult and time consuming. Compression with laparotomy pads in the apical pleura from below and the supraclavicular fossa from above will control hemorrhage while the patient's condition is stabilized and the patient is transported to the operating room.

Figure 17-14 A, Modified umbilical cord clamp. B, Modified umbilical cord clamp securing a catheter in the right atrial appendage.

Figure 17-15 Manual cardiac massage and cross-clamping of the aorta to increase coronary and cerebral perfusion selectively.

appendage is gently grasped between the left thumb and index finger. Scissors are used to create a small opening in the atrial appendage, and a previously flushed catheter is inserted into the right atrium. The umbilical cord clamp is placed over the catheter at the edge of the appendage and snapped shut (Fig. 17-14 B). The cord clamp holds the catheter securely, provides good hemostasis, and does not interfere with the operative field.

## Aortic Cross-clamping

When the systolic pressure cannot be raised above 70 mm Hg, temporary occlusion of the descending thoracic aorta will maintain myocardial and cerebral perfusion (Fig. 17-15) . Dunn and colleagues have demonstrated, using a canine shock model, that aortic cross-clamping is more beneficial to an ischemic heart because of enhanced coronary perfusion than it is detrimental because of increased afterload. [64] Selective clamping is necessary when the aorta has been injured with blunt trauma (Fig. 17-16) . Aortic occlusion has a limited role in controlling hemorrhage below the diaphragm. When there is a tense abdomen with massive hemoperitoneum, aortic cross-clamping is

clearly beneficial when applied just before laparotomy. This has been referred to as *prophylactic cross-clamping* to prevent a sudden drop in blood

pressure when the abdomen is decompressed. [65] As a preoperative procedure, cross-clamping should be applied when the systolic pressure is less than 80 mm Hg in the setting of a tense abdomen.

The aorta lies most immediately anterior to the vertebrae, actually lying on the vertebral bodies themselves. The esophagus lies anterior and slightly medial to the aorta (Fig. 17-17 *A*). To expose the descending aorta, the left lung is retracted in a superomedial direction by an assistant. To achieve adequate exposure, it is sometimes necessary to divide the inferior pulmonary ligament (Fig. 17-17 *B*). The aorta can be quickly identified by advancement of the fingers of the left hand along the thoracic cage toward the vertebral column. On some occasions, the operator may choose to have an assistant simply occlude the aorta with digital pressure. Because both the aorta and esophagus are covered on their anterolateral surface by mediastinal pleura, the pleura must be opened and the aorta bluntly dissected away from the esophagus prior to clamping. To locate the aorta, one uses a DeBakey aortic clamp or a curved Kelly clamp for blunt dissection and spreads open the pleura above and below the aorta (Fig. 17-18) . The esophagus, which lies medially and slightly anteriorly, is separated from the vessel. It may be difficult to separate the esophagus from the aorta by feel in a hypotensive or cardiac arrest situation. A nasogastric tube passed from above may help identify the esophagus. When the aorta is completely isolated, the index finger of the left hand is flexed around the vessel and a vascular clamp is applied with the right hand. The brachial blood pressure should be checked immediately after the occlusion. If the systolic pressure is more than 120 mm Hg, the clamp should be slowly released and adjusted to maintain a systolic pressure of 120 mm Hg. [31]

Given the need for speedy intervention, the simplest and most desirable approach to aortic occlusion is to have an assistant digitally compress it or use the aortic tamponade instrument (Fig. 17-19) (Figure Not Available) . The application of vascular clamps is fraught with complications, which include inadvertent

dislodgment or inadequate occlusion as a result of improper application. The aortic tamponade instrument, however, may be applied blindly to the vertebral column, permitting safe, quick, and complete aortic occlusion. [66] This technique may be the most prudent when isolation of the aorta is difficult. The instrument's unique shape allows it to remain in place and to provide atraumatic occlusion with little interference in the operative field compared to digital compression. The degree of occlusion can be

varied by the amount of pressure exerted by the operator.

Potential complications of aortic cross-clamping are multiple: ischemia of the spinal cord, liver, bowel, and kidneys as well as iatrogenic injury of the aorta and the esophagus may occur. Failure to monitor blood pressure every 60 seconds during aortic occlusion may result in cerebral hemorrhage or left ventricular failure if pressure elevation is excessive. Fortunately, these complications are infrequent. In a report of 12 patients surviving ED thoracotomy with cross-clamping for as long as 60 minutes, no lasting impairments of renal, myocardial, or neurologic function were noted. [67] Whenever possible, the aorta was unclamped for 30 to 60 seconds every 10 minutes to increase renal perfusion. Final release of the aorta is always performed gradually.

## INTERPRETATION AND HEMODYNAMIC MONITORING

Following emergency thoracotomy, the systolic blood pressure after the first 30 minutes of resuscitation may be used as a decision point for further treatment. A report of ED thoracotomies for blunt and penetrating trauma from Denver General Hospital related the hemodynamic response to thoracotomy to patient outcome. [68] Of the 146 cases reviewed, 45 patients (31%) were transferred to the operating room following initial resuscitation and aortic cross-clamping when necessary. For those patients who survived with full neurologic recovery, the average systolic blood pressure after the first 30 minutes of resuscitation was 110 mm Hg. In those who were long-term survivors but had significant brain damage, the average systolic blood pressure was 85 mm Hg. No survivals were recorded when the mean systolic blood pressure was less than 70 mm Hg. Thus, the blood pressure response to emergency thoracotomy is predictive of survival. For patients who remain lifeless with systolic blood pressures below 70 mm Hg despite control of hemorrhage, volume replacement, and cross-clamping for 30 minutes, Moore and colleagues recommend that heroic measures be discontinued. [68] Transfer of these patients to the operating suite for definitive repair would be nonproductive.

## COMPLICATIONS

A variety of postoperative complications may occur in patients surviving emergency thoracotomy. Most of these complications stem from the particular injuries of each patient and must be considered on an individual basis. The complications of open-chest resuscitation are relatively insignificant when compared with a fatal outcome. Two post-thoracotomy complications are frequently discussed. One is thoracic sepsis. This is a rare complication, and excessive concern with

**Figure 17-18** A, Identification of the aorta: in the posterior mediastinum the aorta lies directly anterior to the vertebral bodies. The esophagus is anterior and slightly medial to the aorta. In the lower thorax, both are covered on the anterolateral surface by mediastinal pleura, which must be dissected prior to isolating the aorta for cross-clamping. *B,* Aortic cross-clamping: using blunt dissection, one spreads the pleura above and below the aorta. The vessel should be fully mobilized and clearly separated from the

esophagus before clamping. It may be difficult to differentiate the aorta from the esophagus. The aorta is the more posterior structure and is in contact with the vertebral bodies. Passage of a nasogastric tube from above will often aid the rapid identification of the esophagus.

antiseptic skin preparation may unnecessarily delay a thoracotomy. [69] In a combined series of 142 ED thoracotomies, there were no reports of wound infections. It should be noted that most patients received antibiotics just before or

**Figure 17-19** (Figure Not Available) The use of a Conn aortic compressor is the method of choice for aortic occlusion, because it is fast, does not interfere with the operative field, and is associated with minimal risk of injury. Alternatively, the more awkward technique of direct digital occlusion can be employed. *(Courtesy of Pilling Company, Ft Washington, Pa.)*

during the procedure. Thus, the concern for infection as a complication of a thoracotomy performed with less than sterile technique is unwarranted, although a short course of antibiotics should be administered as soon as possible.

A second complication that is frequently feared and may unfortunately deter a life-saving thoracotomy is the imagined threat that the patient will survive but will be in a vegetative neurologic state. This complication is also rare, and such apprehension appears unjustified. Likewise, the concern of "tying up intensive care unit beds" with patients who have "fatal" injuries has been overemphasized. The first 24 hours following injury will rapidly demonstrate which patients will become long-term survivors. The San Francisco experience with 168 emergency thoracotomies for mixed trauma illustrates that most patients with fatal injuries die within 24 hours. [48] Of patients surviving the first 24 hours, 80% (33 of 41) recovered and left the hospital. Full neurologic recovery occurred for 90% of these survivors. Overall, only 2.4% (4 of 168) remained severely disabled or in a persistent vegetative state. Of these 4 patients, only 1 (0.6%) lived beyond 2 months; he eventually died at 14 months from sepsis.

Moore and colleagues in Denver, describing 146 emergency thoracotomies for mixed trauma, reported 15 patients who survived resuscitation in the operating suite. Eighty percent (12 of 15) of these patients went on to become long-term survivors; 75% had full neurologic recovery. In the Denver study, 2 valuable observations were made regarding the presence or absence of various signs. First, all survivors

with full neurologic recovery had respiratory efforts at the scene; in 75% of these patients, respiratory efforts were still present on arrival in the emergency care unit. Second, the presence or absence of a palpable pulse is not an absolute prognostic indicator. Sixty-six percent of long-term survivors (11 patients with penetrating trauma and 1 with blunt trauma) had no detectable pulse on arrival in the emergency care unit. [68]

A final complication is injury to the resuscitative team. In an emotionally charged environment in which many physicians are attempting to perform life-saving surgery under the harshest of conditions, it is easy to suffer a needle stick or scalpel or scissors injury. Because some victims of penetrating injuries are HIV positive, the need for extreme caution is obvious. Because thoracotomy exposes personnel to a large amount

of blood, universal precautions should be rigorously followed.

## CONCLUSION

The growing incidence of penetrating trauma coupled with advances in out-of-hospital care have increased the number of patients who require advanced resuscitation. For selected patients, an emergency thoracotomy will substantially reduce morbidity and mortality. The effectiveness of this procedure for resuscitation has been well documented. The mechanism of injury and the status of "vital signs at the scene" and on arrival at the hospital should be considered before an emergency thoracotomy is performed. Victims of penetrating trauma who had any vital signs at the scene are candidates for resuscitative thoracotomy and have a chance of survival. This procedure is most effective when it is used to prevent, rather than to treat, a cardiac arrest. In contrast, the survival rates for victims of blunt trauma are negligible. With blunt trauma, resuscitative thoracotomy generally should be considered only when vital signs are still present on arrival at the emergency care unit.

Five factors are closely associated with patient outcome following resuscitative thoracotomy: (1) mechanism of injury; (2) ECG activity; (3) presence or absence of pulse and respiratory effort at the scene and on admission; (4) presence of neurologic function at the scene and on admission; and (5) systolic blood pressure after aortic cross-clamping. The following guidelines should be considered:

1. Blunt trauma victims who lose their vital signs en route to the ED rarely survive despite thoracotomy, and they generally should not be candidates for resuscitative thoracotomy.
2. Penetrating trauma victims who lose their vital signs en route to the ED may still survive and should receive an immediate thoracotomy.
3. Pericardiocentesis (or possibly a subxiphoid pericardial window) should be considered when the systolic blood pressure cannot be maintained above 60 mm Hg with aggressive management and while preparations are made for resuscitative thoracotomy (see Chapter 15) .
4. Further efforts generally should be discontinued following thoracotomy when traumatic arrest patients do not exhibit cardiac activity or tamponade.
5. Consider discontinuing further efforts following thoracotomy if the systolic pressure cannot be raised above 70 mm Hg after 30 minutes of maximum management.

Debate about who should perform an emergency thoracotomy is not necessary. It stands to reason that whoever uses this resuscitative procedure must be prepared to manage the patient. Emergency physicians must possess the knowledge and skills necessary to enable the optimal survival of as many patients as possible. However, it is currently *not* a standard of care that all EDs have the capability of performing an emergency thoracotomy in the absence of surgical backup. Because aortic cross-clamping is only temporizing and should not exceed 30 minutes, rapid transfer of the thoracotomy patient to the operating room is desirable. Whenever possible, a preestablished plan of chest wound management and post-thoracotomy care should be established with the emergency physician's surgical backup. With such a plan, a team

approach to resuscitation and, hence, optimal patient care is possible.

# Chapter 18 - Pediatric Vascular Access and Blood Sampling Techniques

**Frank J. Cunningham Jr.** , **William A. Engle,  Frederick J. Rescorla**

The tasks of sampling blood and obtaining vascular access in an infant or child can challenge and frustrate even the most skilled emergency physician. Unsuccessful attempts on tiny or seemingly nonexistent veins or arteries can consume valuable time, especially when dealing with a critically ill or injured child. The use of invasive monitoring techniques with arterial and central venous catheters is commonplace in contemporary pediatric emergency and intensive care.

This chapter reviews the basic principles and techniques of blood sampling, as well as selection and placement of intravenous (IV) and intra-arterial catheters in infants and children. The use of umbilical catheters in newborns is also reviewed. Although rarely required, emergency cutdown is occasionally life saving, and a section of the chapter is devoted to this technique. Many patients require long-term parenteral nutrition delivered through a centrally placed venous catheter; the techniques for placement of these catheters from peripheral and central venous insertion sites are also described.

## PATIENT PREPARATION AND RESTRAINT

The fear of pain associated with painful procedures and injections makes the hospital experience a traumatic one for children. Therefore, prior to beginning any painful procedure in a child, the procedure itself and the reasons for it should be explained to the parents. In children capable of understanding, the procedure should be explained in developmentally appropriate language before starting and prior to each successive step. The use of deceptive phrases such as "This won't hurt" should be avoided. A simple and honest explanation that the procedure will hurt a bit and "it is okay to cry, but not to move" will provide realistic expectations for the child and set limits as well. Depending on the procedure and the preferences of the physician and the family, the parents may be permitted and willing to remain in the room with the child during the procedure. [1] They should have this option. If they remain during the procedure, their role should be solely to provide comfort and solace to the child and not to assist in any potentially painful procedure. Distracting the child with simple conversation regarding school, friends, hobbies, pets, or television shows can also decrease the level of the child's anxiety. Parents can become patients themselves, and despite their seeming braveness or composure, the potential for parents to faint at the site of blood or needles should always be addressed. Parental injury under such circumstances can be a source of litigation against the physician.

The success of painful procedures such as blood sampling or obtaining vascular access is dependent on proper positioning and restraint of the patient. In most cases this requires the assistance of at least 1 other person. For most procedures this entails restraint of the extremity a joint above and below the intended insertion site. The topical use of lidocaine-prilocaine (Emla) cream has proven particularly useful in relieving pain

associated with needle puncture. [2] [3] However, optimal analgesic results require application 1 hour prior to the procedure, which may not be satisfactory in some clinical settings or in busy emergency departments (see Chapter 31) .

# BLOOD SAMPLING TECHNIQUES

Blood samples for biochemical and hematologic analyses and blood gas analyses may be obtained from indwelling vascular lines. However, capillary, arterial, and venous blood sampling are the principal methods for obtaining blood samples (especially blood cultures) from patients presenting with acute medical or surgical problems. In the sick newborn and young infant, procuring blood samples may be difficult, because many clinicians are not experienced in the techniques of blood sampling in this age group. [4] This section reviews these techniques as they pertain to the newborn and young infant.

## Capillary Blood Sampling

### Indications and Contraindications

Capillary blood sampling, or heel stick puncture, is a frequently used technique to obtain blood samples in young infants. In older children and adults, this technique may be used to obtain blood samples from the finger, toes, and ear lobe. It is most appropriate for patients who require repeated sampling, because the number of times small arteries and veins can be entered successfully is limited, as is the total number of vessels available in small infants. Capillary blood sampling is most often indicated whenever an adequate sample of blood can be obtained by the heel stick puncture technique and when an alternative technique (i.e., indwelling catheter) is not more readily available. It is especially useful for obtaining "arterialized" blood for blood gas analysis when arterial access is unavailable, as in many chronically ill neonates and young infants. Noninvasive monitoring techniques such as pulse oximetry and transcutaneous oxygen monitoring (see Chapter 6) have reduced the frequency with which these samples must be taken.

Sampling from an area of local inflammation or hematoma should be avoided. Also, repetitive sampling from the same site may induce inflammation and subsequent scarring and hence should be avoided. In general, heel stick sampling is not ideal for blood gas analysis (1) when the infant is hypotensive, (2) when the heel is markedly bruised, or (3) when there is evidence of peripheral vasoconstriction. Capillary blood does not always produce an accurate analysis of arterial $P_{O2}$ . When the capillary $P_{O2}$ is >60 mm Hg, the arterial $P_{O2}$ may be considerably higher, with possibly dangerous consequences to infants receiving supplemental oxygen. In this situation the use of either a transcutaneous oxygen saturation or a transcutaneous $P_{O2}$ monitor may allow adjustment of the inspired oxygen concentration until either an arterial $P_{O2}$ or a repeat capillary $P_{O2}$ can be obtained. [5] [6]

### Equipment and Setup

The necessary equipment for capillary blood sampling is shown in Table 18-1 . A 3-mm

lancet (Becton-Dickinson, Rutherford, NJ) should be used to perform this procedure; a scalpel blade should never be used. The use of a 3-mm lancet will prevent the puncture from penetrating more than the maximum safe distance. The full 3 mm of the lancet should be used; a more superficial incision will not bleed adequately. Blood collection is performed using either heparinized capillary tubes or 1-mL Microtainer tubes with a collector attachment (Becton-Dickinson, Rutherford, NJ). If capillary tubes are used, a clay sealer will be needed to close off one end.

| **TABLE 18-1** -- Equipment for Capillary Blood Sampling |
| --- |
| Warm wet towel or diaper |
| Alcohol pads |
| Lancets |
| Blood collection tubes (capillary tubes or Microtainers) |
| Clay sealer (used with capillary tubes) |
| Sterile bandage |
| Nonsterile examination gloves |

**Figure 18-1** *A,* The heel stick is performed on the lateral or medial aspect of the heel. *B,* The collector end of the Microtainer is touched to the drop of blood, and blood is allowed to flow down the wall of the tube to the bottom. Avoid squeezing the foot, and keep the proximal end of the Microtainer below the

**Technique**

Although capillary blood sampling may be performed by the finger stick or heel stick methods, the latter will be described. The recommended sites for heel stick puncture are the medial-most and lateral-most portions of the plantar surface of the heel. [7] This avoids penetration of the calcaneus and the risk of osteochondritis. Prewarming the foot in a warm towel or disposable diaper soaked with warm water for approximately 5 minutes will produce hyperemia and will enhance blood flow. The foot is immobilized in a dependent position with one hand. After the heel is cleansed with alcohol and allowed to dry, the skin is punctured with the lancet (Fig. 18-1) . Although it is tempting and common to do so, *squeezing of the foot should be avoided*, since this may inhibit capillary filling and may actually decrease blood flow. Furthermore, squeezing may dilute the sample with serum or tissue fluid and make analysis less accurate. If blood does not flow freely, another puncture may be required.

The first small drop of blood is wiped away with gauze, and another drop is allowed to form. A heparinized capillary tube is placed in the drop of blood, and the proximal end of the inverted tube is allowed to fill by capillary action. The tube (or tubes, if several tests will be needed) is sealed at one end by sticking the end into wax before the tube is sent to the laboratory. If 1-mL Microtainer tubes are used, the tube is held at an angle of 30° to 45° from the surface of the puncture site. The collector end is touched to the drop of blood, and blood is allowed to drain into the tube. Gentle tapping of the tube will facilitate flow to the bottom of the tube. For heparinized tubes, blood should be collected until the level reaches the demarcation on the tube. Over- or underfilling of the tube may result in clotting and/or erroneous test results. Once an adequate specimen is obtained, a dry dressing is applied to the puncture site.

When a heel stick is performed for arterialized blood samples, the technique used is similar to that discussed previously for routine blood sampling, with the following differences: The infant's foot must be wrapped with a warm cloth for a few minutes. The first drop of blood must be

discarded and the remaining blood allowed to flow freely into a heparinized capillary tube. The tip of the tube should be placed as near the puncture site as possible to minimize exposure of the blood to environmental oxygen. Collection of air in the tube as well as excessive squeezing of the foot should be avoided, because this may artificially lower the $P_{O_2}$ . Approximately 0.2 to 0.3 mL of blood should be collected in the heparinized capillary tube.

**Complications**

When properly performed, heel sticks are associated with a low incidence of complications. Lacerations should not occur when the procedure is performed with a lancet rather than a scalpel blade. Heel sticks may cause infection (local infection, bacteremia, or osteomyelitis), scarring, and calcified nodules. [8] [9] [10] When the heel stick technique is used for the procurement of "arterialized" blood for pH, $PCO_2$ , and

P$o_2$ analysis, the most important potential error is that false information (inaccurate P$o_2$) may result in exposure of the infant to improper amounts of supplemental oxygen.

### Interpretation

Numerous studies have compared the reliability of capillary blood with that of arterial blood for determination of pH, P$CO_2$, and P$o_2$. [11] [12] [13] [14] [15] Although the results have been quite variable, most investigations have documented a close correlation between arterial and capillary samples for pH and P$CO_2$ determinations (except when the patient is in shock or has an extremely high P$CO_2$). Unfortunately, the P$o_2$ determination has not been found to be as reliable when performed on blood obtained by capillary or "arterialized" sampling. Most studies indicate that the capillary (heel stick) P$o_2$ correlates poorly with the arterial P$o_2$, especially if the arterial P$o_2$ is >60 mm Hg. For example, a capillary P$o_2$ of 70 mm Hg may reflect an arterial P$o_2$ of 70 to 200 mm Hg. In nearly all situations, the capillary P$o_2$ is equal to or less than the arterial P$o_2$, but in any individual case, one does not know how closely the capillary value approximates the arterial level. Therefore, *reliance on a capillary sample of blood for P$o_2$ measurement in an acutely sick infant may be fraught with potential risks*. "Arterialized" blood samples obtained from finger and toe sticks might be more reliable for P$o_2$ determination than those obtained from heel sticks, but again, the data are controversial. [16] [17] [18]

## Venipuncture

### Indications and Contraindications

Although many laboratory tests for the small infant may be performed on blood obtained by heel sticks, larger volumes of blood may be required, making heel sticks impractical. Venipuncture is the usual method used for obtaining larger quantities of blood as well as samples for blood culture. Femoral venipuncture for blood samples is discouraged, especially in children <1 year of age, due to the risk of septic arthritis of the hip. [19] In an emergency setting or when few venous access sites exist, blood for laboratory analysis may be obtained from an arterial puncture.

### Equipment and Setup

The equipment required for venipuncture in an infant or child is listed in Table 18-2 . A small-gauge butterfly needle

| **TABLE 18-2** -- Equipment for Venous Blood Sampling in Infants and Children |
| --- |
| A 3-, 5-, or 10-mL syringe |

| |
|---|
| A 21- or 23-ga butterfly needle |
| Evacuated blood tubes |
| Tourniquet (small drainage tubing for infants and children; elastic band for newborns and small infants) |
| Alcohol pads |
| Povidone-iodine swabs (if blood cultures are needed) |
| Sterile 2 × 2-in. or 4 × 4-in. gauze pads |
| Nonsterile examination gloves |

is usually preferred over a needle and syringe for obtaining blood in infants. It is difficult to manipulate standard needles and syringes in tiny veins, and better control is obtained with the butterfly needle. Suction is also more controlled with the butterfly needle and syringe. The butterfly needle may also serve as an infusion line once adequate amounts of blood are obtained. If a straight needle and syringe are used, the technique is similar to that described later for percutaneous arterial puncture, except that a peripheral vein is punctured. The 23-ga butterfly needle will suffice in most venipunctures regardless of age group. In older children and adolescents, the Vacutainer system (Becton-Dickinson, Rutherford, NJ) can be used. However, the negative pressure within the evacuated blood tube, once connected, may be sufficient to collapse the punctured vein. Therefore, a sterile syringe with a 23-ga butterfly attached is preferred. Likewise, a 3- or 5-mL syringe is less likely than a 10-mL syringe to cause vein collapse in young infants. Appropriate restraints and assistance are needed with most pediatric procedures.

**Technique**

Like adults, the usual site for venipuncture in infants and children is the antecubital fossa. However, any reasonably accessible or easily visible peripheral vein (e.g., on the scalp, the hands, or the feet) may be used (Fig. 18-2) . Veins on the dorsum of the hand

can be used, providing they will not be needed for IV cannulation. The external jugular veins and femoral veins are rarely used. When venous access is unavailable, arterial blood may be used for most laboratory tests, including blood cultures.

All needed equipment should be assembled and ready for immediate use. Drawing blood from a small infant is usually a 2-person procedure. It should be emphasized that immobilization of the extremity is mandatory. An assistant should withdraw the blood while the physician concentrates on keeping the needle within the vein and immobilizing the arm. The butterfly needle and the syringe can be attached either before or after skin penetration. However, if done before, the assembly should take place out of sight of the child. To minimize the number of venipuncture attempts, the optimal site for needle insertion should be chosen after a survey of the most prominent peripheral veins. If an extremity vein is to be used, a tourniquet should be applied proximal to the selected vein; in small infants, a rubber band will serve as an adequate tourniquet, but one must be certain to remove the rubber band following venipuncture.

The tourniquet should not be so tight as to impede arterial filling. The area surrounding the chosen site of skin penetration is cleansed with alcohol and allowed to dry.

**Figure 18-2** Venous access sites in the neonate and young infant. If venous access is unavailable, arterial blood may be used for most laboratory tests, including blood cultures.

Slight distal traction is applied to the skin to immobilize the vein, and the needle is inserted quickly through the skin and slowly into the vein at an angle of approximately 30°, with the bevel up (Fig. 18-3 *A*). Successful venous penetration is heralded by a flashback, or flow of blood into the butterfly tubing. *Gentle suction is applied by slowly withdrawing the plunger of the syringe.* Alternatively, suction may be applied with a Vacutainer system in which the Vacutainer needle punctures the sealed end of the butterfly device (see Fig. 18-3 *B*). If the suction is excessive, the vein will collapse, and blood flow will stop. If the required amount of blood is more than the capacity of the attached syringe, the tubing is pinched off, the filled syringe is removed, the next syringe is attached, and gentle suction is once again applied after release of the pinched tubing. After the required amount of blood is withdrawn, the needle is removed, and a sterile dressing and direct pressure are applied to the puncture site.

Although peripheral venous sampling (antecubital, scalp, hand) and arterial sampling are preferable, the external jugular and femoral veins may be used in infants for the performance of a venipuncture during resuscitations or when peripheral sites are inadequate. The external jugular vein lies in a line from the angle of the jaw to the middle of the clavicle and is usually visible on the surface of the skin. The vein is more prominent when the infant is crying. An assistant is needed to restrain the infant in a supine position with the head and neck extended over the edge of the bed. Alternatively, a towel roll or pillow placed under the shoulders can be used. The head is turned approximately 40° to 70° from the midline (Fig. 18-4) , and the skin surrounding the area to be punctured is cleansed with alcohol. Lidocaine (0.1 mL of a 1% solution) may then be infiltrated into the skin. A finger may be placed just above the clavicle to distend the jugular vein. Using a 21- to 25-ga straight needle with a syringe or a 21- to 25-ga butterfly needle attached to a syringe, the clinician punctures the skin and advances the

needle slowly until the jugular vein is entered. The syringe is connected to the needle at all times to maintain a constant negative pressure and avoid an air embolism. After the appropriate amount of blood is obtained, the needle is withdrawn, and slight pressure is applied to the vessel. The infant should be placed in an upright position after the needle is removed, and slight pressure should be continued for 3 to 5 minutes. Close observation of the puncture site should follow.

The femoral vein lies medial to the femoral artery and inferolateral to the inguinal ligament (Fig. 18-5) (Figure Not Available) . The use of this vein for blood sampling is reserved for situations in which patients present in extremis and no other sampling sites are present. An assistant positions the hips in mild abduction and extension while the artery is palpated and its location identified by placing a mark on the abdomen just superior to the femoral triangle (see Fig. 18-5) (Figure Not Available) . The femoral

**Figure 18-3** *A,* Technique for obtaining blood by antecubital venipuncture with a butterfly needle and a syringe. Once blood is obtained, the butterfly needle may serve as an infusion site. Note that this procedure often requires 2 persons to carry it out--one to hold the arm and insert the needle and the other to aspirate the blood. *B,* As an alternative to a syringe, a Vacutainer system may be used to apply suction. The Vacutainer needle punctures the sealed end of the butterfly set. Use of this method helps to prevent the premature clotting of blood that may occur if there is a delay in filling the collection tubes.

**Figure 18-4** External jugular venipuncture. A syringe or a butterfly needle may be used. Venous distention is aided when an assistant's finger occludes the vein, or when the infant cries. The neck is extended, either over the side of the bed or by placing a rolled towel under the shoulders. This procedure requires 2 persons to perform it. Gloves should be worn.

triangle is then prepared with alcohol; a povidone-iodine scrub is also recommended when obtaining blood cultures. The skin puncture site may then be infiltrated with 0.1 mL of 1% lidocaine. The technique of needle insertion is similar to that for external jugular venipuncture (see Fig. 18-4) . The clinician punctures the skin and then directs the needle or catheter toward the umbilicus at a 30° to 45° angle to the skin, remaining medial to the femoral artery pulsation. A slight constant negative pressure is applied throughout insertion. After the needle enters the femoral vein, the desired blood samples are withdrawn, and the needle or catheter is removed (unless venous access with an IV catheter is desired). Pressure is applied to the femoral triangle for a minimum of 5 minutes, and the site is observed closely for recurrent bleeding.

**Complications**

Complications of venipuncture include hematoma formation, local infection, injury to structures adjacent to vessels, and phlebitis. All of these complications are uncommon. Special care should be used when puncture of the external jugular vein or femoral vein is attempted. Inadvertent deep puncture in the neck can produce injury to the carotid artery, the vagus or phrenic nerve, or the apex of the lung. In the femoral triangle, injury to the femoral artery, femoral nerve, and hip capsule may occur. [19] [20] [21] However, such structures are unlikely to be injured when proper technique is practiced.

## Blood Cultures

Although the heel stick capillary tube procedure has been used in some centers for the procurement of blood from infants for cultures, [22] [23] there is a significant incidence of false-positive results with the technique, and therefore it is not recommended if venous blood is available. Venipunctures continue to be the main source of blood for culture in small infants. In the newborn infant, blood may be obtained for culture from an umbilical arterial or venous catheter, if it is obtained immediately after sterile insertion; even then, there is considerable controversy concerning the incidence of false-positive cultures. Arterial blood may also be used to obtain blood cultures.

**Figure 18-5** (Figure Not Available) *A,* Anatomy of the femoral triangle. The vein is always medial to the artery. *B,* The needle insertion site is located 1 finger width below the inguinal ligament, just medial to the artery. Use the index and middle finger to identify the course of the femoral artery. The needle is pointed medially toward the umbilicus at a 45° angle from the skin surface. *(From Pediatric Advanced Life Support Drug Lecture Slides, 1990. Reproduced with permission. Copyright American Heart Association.)*

### Technique

The technique of venipuncture for a blood culture is similar to that described previously for general blood sampling, with the following differences: The puncture site should be doubly prepared, first with a povidone-iodine solution (allowed to dry completely) or with alcohol applied vigorously for 30 seconds (see Chapter 74) . Following completion of the procedure, all of the iodine solution should be removed from the infant's skin to prevent irritation. The volume of blood required for a blood culture depends on the size of the infant. In the neonate with bacteremia, there is a greater number of organisms per milliliter of blood [24] ; a sample size of 0.5 to 1 mL is probably sufficient. In older infants, 2 to 3 mL of blood is ideal. After the appropriate volume of blood is withdrawn, the needle that was used to penetrate the skin is removed, and a sterile needle is attached to the syringe. Half of the specimen should be placed in an anaerobic culture bottle and half in an aerobic bottle.

## Arterial Blood Sampling

### Indications and Contraindications

Arterial blood gas evaluation provides useful information that is essentially unavailable by other means (see Chapter 19) . The arterial blood gas determination is an important laboratory test for evaluation of respiratory status and acid-base equilibrium in infants or children in respiratory distress or shock or with possible medication overdosage. Arterial blood may also be used for routine laboratory analysis if venous blood is difficult to obtain. In fact, if venous access is unavailable, an artery may be used to obtain all laboratory specimens. Possible sites for arterial blood sampling include (1) radial, brachial, temporal, dorsalis pedis, and posterior tibial arteries; (2) umbilical arteries in the newborn infant; and (3) capillaries ("arterialized"). The ulnar artery should not be used for arterial puncture to preserve the collateral circulation to the hand, although some clinicians advocate performing punctures and catheterization of the ulnar artery.

No vein or nerve is immediately adjacent to the radial artery, which minimizes the risk of obtaining venous blood or damaging a nerve. This is not the case with the brachial artery, and the risk of both complications appears to be greater when this artery is used. [25]

The temporal artery is also adjacent to a vein, and if the patient's head is in an oxygen hood, it is nearly impossible to obtain a sample in a steady state. Femoral arteries should not be used for obtaining routine blood samples from the infant or child. [26] Transcutaneous monitoring of $P_{O2}$, $P_{CO2}$, and oxygen saturation may provide useful adjuncts to arterial sampling in many patients. Nonetheless, they do not replace intermittent arterial sampling, which remains necessary for the stabilization of infants and children and for verification of the accuracy of these noninvasive methods. One should avoid puncture of an artery when infection, burn, or other damage to cutaneous defenses exists in the overlying skin.

**Equipment and Setup**

The equipment required for arterial puncture in an infant or child is listed in Table 18-3 . A small-gauge butterfly needle is usually preferred over a needle and syringe for arterial puncture in infants and children. As in venipuncture, a 23-ga butterfly needle is most often used, although in newborns, use of a 25-ga butterfly may be beneficial. Some clinicians prefer to use a 25-ga needle connected to a syringe, but use of a butterfly allows for better control of the needle while an assistant aspirates the syringe and may also permit a larger volume of blood to be withdrawn.

| **TABLE 18-3** -- Equipment for Arterial Blood Sampling in Infants and Children |
| --- |
| Heparin flush solution (10 units/mL) |

| Nonsterile examination gloves |
| Sterile 2 × 2-in. or 4 × 4-in. gauze pads |

Since the radial artery (Fig. 18-6) is most frequently used to obtain intermittent arterial samples from infants and children, the technique for it will be described. Although the merit of the Allen test (see Chapter 19) has been challenged, it is prudent to first assess the adequacy of collateral circulation in the hand. Both radial and ulnar arteries are compressed. After a short time, compression of the ulnar artery is released while the radial artery remains compressed. Adequacy of collateral flow to the hand by the ulnar artery is marked by return of color to the hand. One should then heparinize a tuberculin syringe. All heparin should be ejected from the syringe; a 23- or 25-ga butterfly needle should then be attached to the syringe. The amount of heparin coating the barrel of the syringe is adequate to anticoagulate the sample; excess heparin may result in inaccurate $P_{CO2}$ determinations because of dilution of the blood sample. [27] [28]

The clinician should hold the infant's wrist and hand in the left hand (if the clinician is right-handed). The child's hand is held fully supinated with the wrist dorsiflexed. Some clinicians prefer to immobilize the wrist by taping it to a sandbag or another restraint. [29] The pulsations of the radial artery should be palpable just proximal to the transverse wrist creases. A small indentation can be made in the skin with a fingernail to mark the insertion site. The area is cleansed with alcohol. Some practitioners advocate the use of an intradermal wheal of lidocaine. The skin is penetrated at a 30° to 45° angle (Fig. 18-7) , and while the plunger of the syringe is withdrawn, the needle is advanced slowly until the radial artery is punctured or until resistance is met (Fig. 18-8) . In contrast to the procedure in adults, it is necessary in infants to provide continuous suction on the plunger of the syringe. One can be sure that the radial artery is punctured when blood appears in the hub of the needle. Other clinicians prefer to attach the syringe to the butterfly needle only after blood return is noted; suction is thereafter applied. One may place a transilluminator on the underside (dorsum) of the neonate's wrist to visualize the radial artery. [29]

**Figure 18-7** For arterial blood sampling, the needle should be inserted under the skin at a 30° to 45° angle. A butterfly needle and syringe are used if larger volumes of blood are required. The wrist is held dorsiflexed by the nondominant hand.

If resistance is met while pushing the needle deeper, the needle is slowly withdrawn to the point at which only the distal needle tip remains beneath the skin, and then the procedure is repeated. After 0.3 mL of blood is obtained, the needle is removed, and light pressure is applied for 5 minutes or longer to prevent any bleeding. [30]

A simulator (Medical Plastics Laboratory, Gatesville, Texas) may be used to teach and practice the technique of radial artery puncture in infants. [30]

### Complications

The complications of radial artery puncture include infection, hematoma formation, scar formation, tendon injury, arteriovenous fistula formation, and nerve damage. [31] [32] With the use of proper technique, however, the complication rate is extremely low. The most common concern with puncture of a radial artery (or any peripheral artery) in infants is that the infant may start to cry before blood is obtained, thus changing the $P_{O_2}$ and $P_{CO_2}$ from the values of the quiet state. [33] [34]

Another potential problem is the dilutional effect of heparin on the $P_{CO_2}$. The heparin in the dead space of the

**Figure 18-8** Resistance met during passage of the blood gas needle usually indicates contact with bone. The needle should be withdrawn slowly. If the needle has traversed both walls of the artery, blood will be obtained as the needle is slowly withdrawn into the arterial lumen.

tuberculin syringe may decrease the $P_{CO_2}$ by 15% to 25% when 0.2 mL of blood is obtained and by approximately 10% with 0.4 mL of blood. This emphasizes the need for all heparin to be ejected from the dead space of the syringe *before the needle is applied*. The use of a syringe (e.g., Becton-Dickinson 1-mL U-100 insulin syringe) with minimal dead space or the use of lyophilized heparin eliminates this problem (see Chapter 19)

## VASCULAR LINE PLACEMENT: VENOUS AND ARTERIAL

Intravascular lines are indicated when access to the venous or arterial circulations is necessary. An IV line may be positioned in peripheral veins (scalp, hand, forearm, foot, ankle, axilla, thigh) or central veins (superior vena cava via the internal jugular, axillary, superficial temporal, posterior auricular, or subclavian venous approach [36] [37] and the inferior vena cava via the umbilical or femoral venous approach) (Fig. 18-9) . Likewise, intra-arterial lines may be positioned peripherally (radial, posterior tibial, dorsalis pedis, or superficial temporal arteries) or centrally (abdominal or thoracic aorta via an umbilical or femoral artery approach). Techniques to secure access to these intravascular spaces are discussed in the following sections (see Chapters 19 and 20) . Note that 50% nitrous oxide in oxygen administration to the patient (see Chapter 35) may facilitate these vascular procedures by reducing pain and anxiety. [38] The use of lidocaine-prilocaine (Emla) cream has been shown to decrease the pain associated with

venipuncture and venous cannulation in children as well. [39] [40]

## Peripheral Venous Catheterization: Percutaneous

### Indications and Contraindications

In general, peripheral IV lines are indicated when the patient is unable to attain medical and nutritional goals with enteral therapy. These lines provide maintenance fluids to support adequate hydration and serve as a route for administering medications. In the acute setting, peripheral IV lines provide a route for administering resuscitative medications and fluids as well as antibiotics.

### Equipment and Setup

Materials needed for placement of a peripheral IV line in an infant are listed in Table 18-4 . The 2 devices commonly used for peripheral IV insertion are the butterfly needle and the plastic over-the-needle catheter. The former ranges in size from 21 to 27 ga. Butterfly needles are used primarily for infusions of short duration and are removed after completion. Examples of such use include certain chemotherapeutic agents as well as single-dose antibiotic administration. Due to their rigid nature, they tend to infiltrate very easily in the active child. Placement in a vein close to a flexor surface is contraindicated. For the most part, over-the-needle catheters, such as Angiocath, Medicut, or Quikcath, have become the mainstay of peripheral venous catheterization. These thin-walled, flexible catheters range in size from 14 to 24 ga. For infants, a 22- or 24-ga catheter will suffice in most cases. The selection of catheter size is dependent on the catheter's intended purpose. In general, the smallest gauge appropriate for the clinical situation should be used. Larger diameter catheters allow for rapid administration of fluids in emergency situations. The use of T-connector extension tubing connected to the catheter after insertion facilitates withdrawal of blood for specimen collection, makes flushing the catheter and maintaining patency easier (especially while taping and securing the IV), and allows for dressing changes without disturbing the IV dressing. [41]

The clear plastic wrapper of the extension tubing package can be taped over the hub of the catheter as a protective covering to prevent accidental dislodgment when snagged on clothing or bed linen or subjected to the wandering

fingers of an inquisitive child. An arm or leg board appropriate for the size of the child should be handy to provide for stabilization of the extremity after insertion. In newborns or small infants, fashioning an arm board from two tongue depressors taped together and covered with 4 × 4-inch gauze will provide the appropriate length needed. One should have primed and ready an IV fluid chamber with microdrip and a continuous infusion pump. Fluid administration in an infant must be carefully monitored. *Macrodrip tubing and liter bottles should not be used*; inadvertent infusion of large amounts of fluids in an infant may be disastrous. An infusion pump is an ideal way of limiting fluid infusion while keeping the vein open.

**Technique**

A number of IV sites are available for placement of a peripheral IV needle or catheter in the infant (see Fig. 18-2) . [36] [37] The most common sites chosen for IV insertion in infants and children are the superficial veins of the dorsum of the hand; the antecubital fossa; the dorsum of the foot; and, in newborns and small infants, the scalp. The veins of the dorsum of the hand are the most often used. These vessels are relatively straight and lay flat on the metacarpals and therefore are stabilized without undue difficulty. If the hand is chosen, one should take into consideration the age and hand preference of the patient. Veins in the antecubital fossa (cephalic and basilic veins) are easily accessible; however, their angulation across the fossa may make advancement of the catheter difficult. These veins may not be easily visible and yet may be palpable. It is recommended to select the most distal vein that is large enough to accommodate the catheter and leave the larger, more proximal veins in case (1) initial attempts are unsuccessful or (2) prolonged IV therapy may be needed and percutaneous central venous catheter placement is contemplated. Tributaries of the dorsal venous arch on the dorsum of the foot, like those on the dorsum of the hand, are relatively straight, and the extremity is easily immobilized after insertion. Because indwelling catheters in this location will prevent mobility, this site should be considered only in preambulatory patients or after attempts at other sites have been unsuccessful. The scalp veins are probably the easiest to cannulate, but their use is primarily limited to infants <1 year of age. If a peripheral vein on the hands, feet, or antecubital fossa is being used, the extremity can first be immobilized by taping it to an arm board, a padded splint, a full plastic IV fluid bag, or a sandbag. The particular site is a matter of preference, and the physician should choose the vein that appears to be the easiest to cannulate.

With few exceptions, the same techniques used for IV insertion in adults may be used in infants and children, especially in the veins of distal extremities. If a peripheral extremity is used, a tourniquet may be placed proximal to the planned site of entry. Although not in widespread use, nitroglycerin ointment (0.4-0.8 mg) is advocated by some physicians to induce local vasodilation, thereby aiding venous cannulation. [42] The tubing of the butterfly infusion set or the T-extension set should be flushed before venipuncture with a sterile IV solution, such as normal saline, to prevent air embolism. If a plastic catheter is

used, the catheter with stylet in place is directed through the skin at a 10° to 20° angle (see Fig. 18-9 A). [43] The catheter with stylet is slowly advanced until blood return is noted. One then advances

the catheter over the stylet into the vein. The stylet is removed, and the IV line is connected to the hub of the catheter by means of a T-extension set. After 1 mL of solution is flushed through the line, the site is inspected for signs of infiltration, such as hematoma or local swelling.

The catheter is fixed to the skin with a piece of 0.5 in. tape passed around and over the catheter hub and fixed to the skin. A second piece of tape is placed adhesive side uppermost under the catheter hub and crossed over the catheter in a V shape (see Fig. 18-9 B). The tubing of the T-extension set is looped back, and a piece of tape is placed midway over the tubing and secured to skin. This ensures against accidental dislodgment if the IV tubing is suddenly pulled. The hand and forearm are securely taped to the arm board for immobilization (see Fig. 18-9 C). The clear plastic wrapper of the extension tubing package is then taped over the hub of the catheter as a protective covering (see Fig. 18-9 D). Occasionally the flow rate of the infusion may be positional, especially if the catheter spans a joint or abuts a venous valve. Careful repositioning or adjustment of the hand position or catheter with strategically placed sterile gauze or slight withdrawal of the catheter may be all that is required to remedy the problem.

If blood specimens and blood cultures are needed, one can obtain these simultaneously during IV insertion and spare the child an additional needlestick. The procedure is similar to venipuncture, with the following exceptions. The T-extension tubing and attached syringe should not contain any flush solution. After appropriate preparation of the insertion site and successful placement of the catheter into the vein, the T-extension tubing and syringe are connected to the hub of the catheter, and the blood is aspirated into the syringe. After the desired quantity is obtained, the syringe is removed, and the T-extension tubing is connected to the IV infusion tubing, and the infusion pump is set at the desired rate.

If the scalp veins are used, the area surrounding the planned site of insertion should be shaved and cleansed with an iodine solution. Arteries and veins can usually be differentiated on the scalp by the fact that arteries are more tortuous than veins. In addition, the flow of blood is away from the heart in arteries and toward the heart in veins. If an artery is entered during placement of the needle and fluid is infused, blanching will occur in the area. If this happens, the catheter or needle should be removed, light pressure should be maintained for several minutes, and the procedure should be repeated at another site. A rubber band may be used as a tourniquet around the scalp *(never the neck)* to produce venous dilation. One should always ensure that the rubber band is removed after venous cannulation. When removing this rubber band, it should be carefully slipped over the catheter or butterfly needle or cut with a pair of scissors. Although cutting the rubber band with scissors is often the easiest technique, the clinician must take care to hold both ends of the cut rubber band to avoid having the infant "snapped" by one or both ends of the rubber band. Placing a piece of tape on the rubber band before placement on the scalp will facilitate lifting the rubber band away

from the scalp.

If a scalp vein butterfly infusion set is used, the wings of the butterfly are grasped between the thumb and forefinger, and the needle is introduced beneath the skin approximately 0.5 cm distal to the anticipated site of vein entrance (Fig. 18-10) . The needle is advanced slowly toward the

**Figure 18-10** Using a rubber band as a tourniquet to distend the scalp veins, the needle is introduced approximately 0.5 cm distal to the anticipated site of the vessel puncture. Gloves should be worn.

vessel until blood appears in the tubing, indicating that the vessel has been entered. The tourniquet should then be removed. The needle should be flushed with 0.5 to 2 mL of IV fluid, such as normal saline, to ensure that the needle is properly in place within the vein. If infiltration occurs, as noted by a subcutaneous (SQ) bump, the IV line should be removed and the process repeated at another site.

After the wings are secured with tape, the tubing of the butterfly set should be taped in a loop on the scalp so that it is not inadvertently pulled. A wisp of cotton may be placed under the wings of the butterfly if the infusion is positional. A small plastic medicine cup or half of a paper cup may be taped over the wings and the needle to protect the IV line (Fig. 18-11) . The catheter of the butterfly set should then be connected to the tubing from the IV system, and the IV pump should be started.

**Complications**

Complications of IV fluid therapy include infection [44] ; injection of sclerosing agents into the SQ space, with resultant necrosis and sloughing of the skin (especially in small infants) [45] ; air embolism [46] ; and administration of inappropriate volumes of fluid. The incidence of infection secondary to peripheral IV therapy may be decreased by routine periodic replacement of the needles. [47] Because the life span of an IV needle or catheter is usually fairly short (<72 hours) in the small infant, the decision concerning elective removal and replacement of the IV system is not usually a problem. Of course, it is important to pay meticulous attention to sterility during insertion and maintenance of the IV system to decrease the risk of infection.

A simulator (Medical Plastics Laboratory, Gatesville, TX) is available to demonstrate and practice the proper technique for placement of peripheral IV needles in infants. [48]

## Peripheral Venous Catheterization: Venous Cutdown

**Indications and Contraindications**

With the development of small IV catheters and butterfly needles and the rapidity and safety of intraosseous (IO)

**Figure 18-11** Protecting the IV line with a plastic medicine cup.

cannulation (see Chapter 26) , peripheral venous cutdowns are rarely used in infants. Even in experienced hands, a saphenous vein cutdown may take >10 minutes, may last no more than percutaneous catheterization, and is associated with a higher rate of infection than other routes of vascular access. [49] [50] Nonetheless, if peripheral venous, central venous, and IO cannulation cannot be performed, venous cutdowns may provide an alternative means of emergency venous access. For the purpose of illustration, the exposure and cannulation of the saphenous vein are discussed (Fig. 18-12) . The same principles apply when a cutdown is performed on an arm vein.

### Equipment and Setup

Successful venous catheterization in the small infant requires sterile instruments, an assistant, good lighting, and a selection of catheters. The use of self-retaining retractors is a personal preference. Because of temperature instability, a warming light or an overhead radiant warmer is frequently useful. Silastic catheters, which can be obtained in 2, 3, and 4 Fr sizes (Dow-Corning Company), seem to remain patent longer, and can be sterilized with the instruments to make a "cutdown tray." Standard 18- to 22-ga IV catheters (Angiocath, Deseret Medical, Inc., Sandy, Utah) are also useful.

### Technique

The clinician should begin with complete immobilization of the thigh, leg, ankle, and foot by taping them to a padded arm board, which in turn is attached to the table or bed where the procedure is being performed (see Fig. 18-12 *A*). The area around the medial malleolus is prepared with a povidone-iodine solution and draped with sterile towels. Local anesthesia is accomplished by superficial infiltration with 0.25 to 1% lidocaine in an area proximal and anterior to the superior portion of the medial malleolus. Fortunately, there are no major nerves or tendons that accompany the vein in this location (see also Chapter 22) .

A tourniquet is placed in the midleg, and a transverse skin incision is made; a small mosquito hemostat is inserted into the wound, with the concavity of the clamp upward. The tip of the hemostat is advanced to the bone in one corner of the wound, and all tissues lying against the bone and in the SQ region are "scooped up" with the hemostat (see Fig. 18-12 *B*). This will invariably lift the vein out of the wound along with surrounding tissues. A fine forceps or a mosquito hemostat is used to separate and remove all nonvenous structures, leaving only the saphenous vein tented over the hemostat (see Fig. 18-12 *C*). To avoid injury to the vein during dissection, one spreads the ends of the hemostat parallel to the direction of the vein, *never* transversely.

Two 4-0 silk sutures are passed under the vein; one silk suture is pulled distally to stabilize the vein, and the other suture is pulled proximal to the site of venipuncture. The distal suture may be tied, but if left untied, it can still be used for stabilization of the vein. Removal of the untied distal suture following vein cannulation may allow for subsequent vein recannulation following eventual catheter removal. If the distal suture is left untied, longitudinal traction on it permits hemostasis and continued exposure of the vein above

the wound. Fine scissors or a scalpel blade may be used to make an oblique or V-shaped incision in the anterior (superficial) vein wall between the sutures (see Fig. 18-12 *D*). The catheter (beveled at its tip) is then filled with saline.

The catheter is grasped with forceps and is advanced into the vein for a distance of 2 to 3 cm (see Fig. 18-12 *E* and *F*). This is usually the most difficult and time-consuming portion of the procedure. A vein dilator or forceps may be used to hold open the incision in the vein (see Fig. 18-12 *G*). Downward pull on the distal tie will give countertraction and will stabilize the vein during catheter advancement. The tourniquet is then removed. One ties the proximal suture around the vein with the catheter inside, taking care not to occlude the catheter by tying the suture too tight. If the distal suture was tied, the free ends of the suture can be tied around the catheter, providing additional stability to the catheter. If the distal suture was not tied, it is now removed. When the distal suture is left untied, the proximal suture is still tied to secure the catheter, but the ends are left long so that the suture can be pulled out of the incision and removed to allow recannulation once the infusion catheter is removed.

Continued infusion of saline through the catheter from an attached syringe will ensure patency. The catheter is oriented into either corner of the incision, and the incision is closed with interrupted 4-0 nylon sutures. The skin suture nearest the catheter is wrapped around the catheter and tied to hold the catheter in place. Bleeding can be controlled with direct pressure. Antibiotic ointment is placed over the wound, and a sterile occlusive dressing is applied. The IV tubing is connected and taped securely to the foot board to prevent inadvertent removal of the catheter (see Fig. 18-12 *H*).

One should change the dressing carefully every day, using sterile technique with reapplication of antibiotic ointment. When cared for properly, catheters can remain in place for as long as 7 to 10 days. Generally, though, a line is replaced, using another site, after 3 to 4 days. Obviously, at the first sign of infiltration or infection the catheter must be removed. Unfortunately, once the vein has been used for a cutdown, it is usually rendered useless for future venous cannulation.

**Figure 18-13** The mini-cutdown procedure using a standard IV catheter over-the-needle system is technically easier than the full cutdown and may be preferred in an emergency.

**Mini-cutdown.**

The cannulation of a small vein with a catheter or tube may be difficult and very time consuming if one is not experienced in the technique. As an alternative, the mini-cutdown procedure may be used. Once the vein is exposed through a skin incision and SQ dissection, it is cannulated directly with a standard IV catheter (Medicut, Angiocath) rather than nicked with a scalpel (Fig. 18-13) . A silk suture or hemostat may be placed under the vein to immobilize it during puncture, but with the mini-cutdown technique, the vein is not tied off after being cannulated. The catheter will not be as secure with this modification, but the technique is useful when time is critical. The vein is not destroyed with this technique. In essence, the mini-cutdown uses the percutaneous technique of cannulation, except that venipuncture is performed through a skin incision

under direct visualization (see Chapter 22) .

**Suggestions**

In an emergency situation, if a percutaneous peripheral or central venous access is not available within several minutes, a saphenous cutdown should be performed (see previous discussion). The technique requires practice and may consume 5 to 15 minutes of resuscitation time. One common error is making an improper skin incision. The incision must be made through all layers of the skin without severing the vein. SQ fat should be visible through the incision. The SQ incision should be carried to the end of the skin incision so that the clinician can take full advantage of the skin incision. A 2-cm incision is usually required, and one should not try to work through a skin incision that is too small.

One should perform dissection only with a blunt technique, spreading the hemostat *parallel to the course of the vein.* Inadvertent severance of the vein may occur during dissection, and one can best control bleeding by pulling the silk ties taut. The incision in the vessel may be a source of frustration. One must incise completely into the lumen of the vessel; a superficial nick, although it will bleed, will not allow for catheter passage. If the vein is severed completely, it will retract from view and will be difficult to find. Generally an incision should include one third of the vessel diameter. Placing the catheter into the vessel lumen is usually the most difficult part of the procedure, and it is easy to create a false lumen. Small plastic vein dilators are available to facilitate entering into the lumen. If a valve is encountered during passage, one should increase the rate of fluid administration while gently advancing the catheter.

**Complications**

In addition to the problems discussed previously, venous cutdowns can result in wound infections and phlebitis. Adjacent structures may be injured during the incision and subsequent blunt dissection. When the mini-cutdown technique without ligatures is used, extravasation of infusate may result. Light pressure on the closed wound will generally prevent continued extravasation.

## Central Venous Catheterization: Percutaneous

Percutaneous placement of central venous lines (CVLs) has become the technique of choice of many clinicians for securing central venous access in neonates and young infants (see Chapter 24) . [49] [51] [52] This technique has largely supplanted the conventional technique of venous cutdown catheterization. Both percutaneous and venous cutdown catheterization require central venous catheters, which can be purchased separately or within self-contained kits (Arrow International, Inc., Reading, PA; Gesco International, San Antonio, TX). However, CVL placement requires little additional equipment, whereas venous cutdown catheterization requires a set of sterile instruments. Percutaneous CVL placement also preserves the access veins for repeated use, whereas the venous cutdown technique has traditionally included ligation of the access vein. Finally, the percutaneous approach avoids the tissue injury associated with surgical incision and dissection. [53] It may be used for rapid venous

access in emergency situations, as well as to secure central venous access when peripheral venous access is limited (e.g., in low-birth-weight infants). [49] [54] [55]

**Indications and Contraindications**

Percutaneous central venous cannulation is indicated to secure vascular access (1) when peripheral venous access is limited or impossible, (2) for emergency drug and fluid administration during cardiac arrest and shock, (3) when hyperalimentation and IV infusions are required for days to weeks, (4) when low-birth-weight neonates and young infants require central venous access, and (5) when precise hemodynamic monitoring is needed in a critically ill or injured child. Contraindications to percutaneous placement of central venous catheters include an uncorrected coagulopathy; local infections or burns at insertion sites; malformations or deformations that may distort vascular anatomy; vascular insufficiency of an extremity; obstruction or compression of the access veins by tumor, abnormal vessels, hematoma, thrombus, abscess, or malformation; absence of access veins; or a planned future transfemoral cardiac catheterization. [55] Bacterial septicemia is a relative contraindication, and delaying placement of central venous access until cultures have been sterile for 48 hours is generally recommended.

**Equipment and Setup**

Percutaneous central venous catheterization in infants and children can be performed using any of a number of sterile over-the-needle catheters ranging in size from 22 to 16 ga

(choice depends on the age of the patient) and equipment similar to that used for percutaneous peripheral venous catheterization. If insertion of a larger indwelling catheter is desired, commercially available kits are convenient (Gesco International, Inc., San Antonio, TX; Arrow International, Inc., Reading, PA; Cook, Inc., Bloomington, IN). The catheters are typically made of a silicone elastomer, polyvinyl chloride, or polyethylene. Catheter length is variable, and 1- to 3-lumen catheters are available. It is important to remember that the flow rate of the catheter is directly proportional to the gauge of the catheter and indirectly related to the length. Rapid volume replacement, as in the case of severe dehydration or acute blood loss from trauma, is best achieved by inserting a short, large-bore catheter for the initial resuscitation and stabilization. If the patient requires hemodynamic monitoring or multiple medication infusions, the catheter can be replaced later with a larger indwelling catheter using the Seldinger technique.

Other necessary equipment includes sterile forceps and scissors, povidone-iodine solution, gauze pads, sterile drapes, gowns, gloves, caps and masks, syringes (3 mL, 5 mL, and 10 mL), Tegaderm (Medical Products, Inc., St. Paul, MN), Op-Site (Smith and Nephew Medical, Massilon, OH), or other sterile transparent skin coverings, Luer-Lok three-way stopcocks, 0.25 to 1.0% lidocaine, flush solution (1 to 2 U heparin per mL normal saline or $D_5W$), and IV tubing with a T-connector extension. Depending on the access vein to be used, restraint of the extremity, pelvis, or head may require a padded support, an assistant, or both.

**Techniques**

Percutaneous placement of central venous catheters can be accomplished using 2 methods that differ only in the use of a guide wire. The guide wire (Seldinger) technique is preferred when catheters are inserted into the femoral vein or subclavian vein. When using the basilic or cephalic vein of the forearm and antecubital space, axillary vein, or superficial temporal or posterior auricular scalp vein, we prefer to insert the catheter through an introducer needle. Some investigators may use the saphenous vein as an access vein. Details of the pediatric femoral, external and internal jugular, and subclavian and antecubital approaches follow.

**Femoral catheterization.**

Previously, central venous catheters were most commonly inserted by cutdown on the external or internal jugular vein or high saphenous vein or by percutaneous cannulation of the subclavian or internal jugular vein. [56]

The safety and efficacy of percutaneous femoral venous catheterization have been demonstrated. [21] [52] [57] Femoral venous catheterization is the central venous access route most commonly used in infants and children in emergency situations. Advantages of this technique are several. The femoral anatomy is easily learned, and the arterial pulse provides a landmark for catheter insertion. In case of inadvertent arterial puncture or venous laceration, hemostasis can be achieved by application of direct pressure. Also, femoral catheterization is less likely to interfere with emergency procedures in the region of the head, neck, and chest during medical or trauma resuscitations. [21] In addition, the specific risks associated with subclavian and internal jugular vein catheterization (pneumothorax and carotid or subclavian artery puncture) are avoided. Risks of the procedure include thrombosis and infection; these can occur with any type of venous catheters.

**Technique.**

The child must be adequately restrained to permit exposure of the inguinal region; sedation may be useful. It may be helpful to use an ultrasonic Doppler flow detector to locate the femoral artery and then place a heavy ink mark on the abdomen in the line of the femoral artery. This may be useful if edema makes palpation of the artery difficult or if the artery is difficult to locate when wearing gloves. Note that during CPR, palpable pulsations or Doppler tones in the femoral vein may be detected. [58] Hence, if the vein is not found medial to the pulsations, catheterization of the pulsating vessel during cardiopulmonary resuscitation (CPR) may be considered as a last resort when other options for vascular access or drug delivery are unavailable. Both groins are generally prepared with povidone-iodine in the event that the initial attempt is unsuccessful.

The introducer needle supplied with the kit can be used with or without a syringe to enter the femoral vein. The femoral artery is palpated with 1 finger, and the needle is placed in the skin just medial to the artery. One enters the skin at a 30° to 45° angle

approximately 1 cm below the inguinal ligament. The general course of the needle is in a line directed toward the umbilicus. When blood return is noted, the wire is gently passed through the needle into the proximal vein. An alternative method that may be useful when placing the 4 Fr double-lumen Arrow catheter is to remove the tubing from a 21-ga butterfly needle (Abbott Hospitals, Inc., North Chicago, Ill) and use the needle to enter the vein (Fig. 18-14 *A*). The butterfly needle is very easy to hold in a stable position and is also shorter than the needles supplied with the assembled kits. When blood return is obtained, the wire is passed through the butterfly needle into the proximal vein.

A small incision (1 to 2 mm) is then made along the wire to allow passage of the vein dilator (Fig. 18-14 *B*). The dilator is removed; the catheter, which has been flushed with saline, is advanced over the wire into the vein; and the wire is then removed (Fig. 18-14 *C*). [59] Occasionally it is useful to rotate and advance the catheter simultaneously as it enters the vein. Blood return is noted from the catheter ports, which are then flushed with a heparinized saline solution (10 U/mL). The catheter is subsequently secured with silk or nylon sutures (Fig. 18-14 *D*). A sterile transparent skin covering placed over the exit site may be used as an impermeable dressing.

This technique is useful in children as small as 1000 gm. When one is placing femoral venous catheters in children <1500 gm, a smaller single-lumen catheter (3 Fr or 24 ga) should be used, because a larger catheter may occlude blood flow in the femoral vein. [4]

**External jugular venous catheterization.**

The external jugular vein is superficial and easily visible. This site should be selected for catheterization only after catheterization of other, more peripheral sites has been unsuccessful. Also, the external jugular vein should not be chosen as a primary catheterization site during resuscitative efforts, since manipulation of the head and neck may compromise management of the airway. In young infants, use of the Seldinger technique is difficult due to the short length of the infant's neck, as well as the low success rate of central venous catheter placement resulting from the acute angle of entry of the external jugular vein into the subclavian vein. [60]

**Technique.**

The external jugular vein lies in a line from the angle of the jaw to the middle of the clavicle and is

**Figure 18-14** Technique for inserting a femoral venous catheter. *A,* A 21-ga butterfly catheter is used to enter the femoral vein, and the guide wire is passed through the butterfly needle into the proximal vein. Note that the tubing has been removed from a standard butterfly set. *B,* A small incision is made alongside the wire, and the dilator is advanced over the wire and into the vein. *C,* The catheter is advanced over the wire and into the vein. *D,* The wire is removed and the catheter secured. Note that

usually visible on the surface of the skin. The vein is more prominent when the infant is crying. An assistant is needed to restrain the infant in a supine position with the head and neck extended over the edge of the bed. Alternatively, a towel roll or pillow placed under the shoulders can be used. The head is turned approximately 40° to 70° from the midline (see Fig. 18-4) . The skin surrounding the area to be punctured is cleansed with alcohol. The area is covered with a sterile drape, and 1% lidocaine may then be infiltrated into the skin. A finger may be placed just above the clavicle to distend the jugular vein.

Using an 18- to 22-ga catheter with a syringe, the catheter is aligned parallel to the vein, and the skin is punctured approximately one half to two thirds of the distance from the angle of the jaw to the clavicle. The catheter is advanced slowly until the jugular vein is entered. The syringe is connected to the catheter at all times to maintain a constant negative pressure and avoid an air embolism. After the appropriate amount of blood is obtained, the catheter is advanced and secured in place. If the Seldinger technique is used, proceed as described for femoral catheterization. The catheter should be passed far enough to reach the superior vena cava-right atrium junction. The catheter is checked for blood return, and the line is secured with sutures and a sterile occlusive dressing applied. [61] A chest radiograph is warranted to assess the proper location of the catheter, as well as to rule out the possibility of an iatrogenically induced pneumothorax.

**Internal jugular venous catheterization.**

The internal jugular veins lie within the carotid sheath containing the carotid artery and vagus nerve. The lower part of the veins lies within the triangle formed by the sternal and clavicular heads of the sternocleidomastoid muscle and becomes more lateral and anterior to the artery as the veins join the subclavian

vein. The right internal jugular vein is preferred over the left, since the internal jugular and innominate vein and the superior vena cava form a nearly straight line into the right atrium. This lessens the chance for pneumothorax or injury to the thoracic duct (see Chapter 24) . Like the external jugular, this site should be chosen for catheterization only after catheterization of other, more peripheral sites has been unsuccessful.

**Technique.**

Three approaches (the anterior, medial or central, and posterior approaches as discussed in Chapter 24) to internal jugular catheterization are possible. The medial or central approach is recommended in pediatric patients and will be described here. The child is positioned in the same fashion as that described for external jugular venous catheterization. The medial or central approach uses the apex of the angle formed by the sternal and clavicular heads of the sternocleidomastoid muscle as the entry site. The skin surrounding the area to be punctured is cleansed with alcohol. The area is covered with a sterile drape, and 1% lidocaine may then be infiltrated into the skin.

Using an 18- to 22-ga needle with a syringe, the needle is introduced at the apex of the triangle at an angle of 30° downward relative to the coronal plane and directed caudally toward the ipsilateral nipple (Fig. 18-15) (Figure Not Available) . The needle is advanced slowly until the jugular vein is entered. The syringe is connected to the needle at all times to maintain a constant negative pressure and avoid an air embolism. After blood flow is obtained, the syringe is removed, and a finger is placed over the hub of the needle. A guide wire is then inserted during a positive-pressure breath or exhalation, the needle is removed, and a catheter is introduced using the Seldinger technique (see Chapter 21) . The catheter should be passed far enough to reach the superior vena cava-right atrium junction. The catheter is checked for blood return, the line is secured with sutures, and a sterile occlusive dressing is applied. [61] A chest radiograph is warranted to assess the proper location of the catheter, as well as to rule

**Figure 18-15** (Figure Not Available) Technique for internal jugular venous catheterization (medial or central approach). The needle is inserted at the apex of the triangle formed by the sternal and clavicular heads of the sternocleidomastoid muscle. The needle is angled 30° downward relative to the coronal plane and directed toward the ipsilateral nipple. *(From Textbook of Pediatric Advanced Life Support, 1994. Reproduced with permission. out the possibility of an iatrogenically induced pneumothorax.

**Subclavian venous catheterization.**

The subclavian vein is a popular route of central venous access in the adult patient but is used far less frequently in children. The technique is more difficult in the child because of the vessels' smaller size, as well as their more cephalad location under the clavicles. An infraclavicular approach to the subclavian vein has been used, but due to the high risks of pneumothorax and hemothorax, especially when performed during emergencies, this approach should be considered only if other peripheral or central venous access sites are unobtainable. [62] [63] The younger the patient, the higher the risks of these complications. Also, subclavian venous access may interfere with resuscitative efforts, and except in very small infants and obtunded children, heavy sedation and adequate restraint are often required.

**Technique.**

The technique for subclavian venous catheterization differs from that for the adult in that the approach to the vein is more lateral in children. The equipment needed is the same as that used for femoral catheterization. The patient is placed in the Trendelenburg position with the head turned away from the side to be punctured and a towel roll placed under the shoulders (Fig. 18-16) (Figure Not Available) . The right side is preferred, since the dome of the lung is more cephalad on the left side. The needle insertion site is at the distal one third of the clavicle in the depression created between the deltoid and pectoralis major muscles. If the patient is awake, sedation should be administered. The skin is prepped with antiseptic solution, the area covered with a sterile drape, and the skin infiltrated with 1% lidocaine.

An entry point is created at this location using a scalpel blade. The catheter needle is

introduced and advanced slowly while negative pressure is applied with the attached syringe. The syringe and catheter needle should be parallel to the frontal plane and directed medially and slightly cephalad, beneath the clavicle toward the posterior aspect of the sternal end of the clavicle (i.e., with the lower end of the fingertip placed in the sternal notch). [64] The needle is advanced until blood return is obtained. The catheter can be advanced a few more millimeters further to ensure its position in the vein. Catheter functioning can be assessed by the ability to withdraw blood and flush saline without difficulty. At this point, a large-bore catheter can be inserted using the Seldinger technique as previously described for femoral catheterization. Auscultation of bilateral breath sounds should be performed and a chest radiograph obtained to confirm the proper positioning of the catheter in the superior vena cava, as well as to rule out procedural complications such as pneumothorax or hemothorax. The catheter is then secured in place with sutures, and a sterile, occlusive dressing is applied.

**Antecubital access.**

Percutaneous insertion of central catheters by way of peripheral antecubital veins is used most frequently to obtain central venous access in patients with very small caliber vessels (e.g., low-birth-weight neonates and very young infants). These peripherally inserted central catheter (PICC) lines are small Silastic catheters ranging in size from 23 to 16 ga. [55] [65] [66] The catheter is inserted through a peripheral vein through a 19-ga butterfly needle or 20-ga angiocatheter. The most common sites include scalp, neck, and arm veins. The catheter is then threaded centrally. PICC lines offer several advantages over conventional peripheral

**Figure 18-16** (Figure Not Available) Technique for subclavian venous catheterization. The needle is inserted at the distal one third of the clavicle in the depression created between the deltoid and pectoralis major muscles. The needle should be parallel to the frontal plane and directed medially and slightly cephalad toward a fingertip placed in the sternal notch. IV catheters and percutaneous central venous catheters. They can remain in place for up to 3 months, sparing vein wasting from multiple reinsertions with peripheral venous catheterizations; the long-arm catheter is simpler to insert than central venous catheters and poses no risk of producing a pneumothorax or hemothorax on insertion. [67]

**Technique.**

The vessel to be cannulated is initially stabilized using a support board or the help of an assistant. The remainder of the procedure requires sterile technique. Povidone-iodine is used to cleanse the skin overlying the vessel to be cannulated, and 0.25% to 1% lidocaine is infiltrated at the skin site to be punctured. This skin site is punctured with an 18-ga needle to ease insertion of the introducer through the skin. The catheter to be inserted is chosen based on the size of the access vessel.

Typically a 23-ga silicone elastomer catheter with other needed accessories is used, as in a kit prepared by Gesco International, Inc. (San Antonio, Texas). Advantages of this

catheter include (1) a double-wing silicone adapter, which precludes the need to make homemade blunt-end adapters to fit small cannulas and simplifies the taping procedure, and (2) a breakaway introducer needle that can be peeled off the catheter, thereby precluding the need for sliding the introducer off the catheter and placing an adapter. Because the length of this catheter (33.5 cm) is longer than needed in low-birth-weight neonates and young infants, the distance from the insertion site to the superior vena cava-right atrium junction is estimated (i.e., by measuring the distance between insertion site and the right nipple [Fig. 18-17 A]), and the catheter is cut 1 to 3 cm longer than the estimated distance to compensate for variability between the estimated and actual needed length of the catheter. The end of this catheter is then connected to a Luer-Lok stopcock and syringe and filled with flush solution; the catheter is then ready for use.

**Figure 18-17** Techniques for insertion of central catheters from peripheral veins. *A,* A tape measure is used to determine the catheter length. *B,* Placement of the catheter through the specialized breakaway butterfly-type introducer needle.

The 20-ga breakaway introducer needle (Gesco International, Inc.) is also filled with flush solution and then directed slowly through the insertion site and into the access vein. When blood return occurs, the catheter is picked up approximately 1 cm from its tip and guided into the introducer needle (Fig. 18-17 B). The catheter is advanced in 1-cm increments until the previously estimated distance is reached (i.e., the catheter tip is at the superior vena cava--right atrium junction). The breakaway introducer needle is then withdrawn several centimeters from the insertion site before peeling the introducer off the catheter to avoid inadvertent catheter laceration. If accidental laceration occurs, blunt-end adapters should be readily available.

Immediately after catheter placement and withdrawal of the introducer needle, the clinician will be able to manipulate the position of the catheter. Once clotting occurs around the catheter at the insertion site, however, the catheter becomes difficult to manipulate. In addition, after the sterile field is discontinued, the catheter should never be advanced. The function of the catheter is checked by withdrawing blood, by noting the presence of residual air bubbles within the catheter, or both. After the clinician is assured that no air bubbles remain in the line, the catheter is flushed. This catheter should be "easy" to flush; if it is not, the clinician should reposition the catheter and recheck its function. If the catheter remains difficult to flush, it should be considered clotted and should be removed. Alternatively, position may be confirmed by chest radiograph and fibrinolytic therapy used, if considered appropriate.

A transparent skin covering is placed and is removed only when the catheter is removed; it is not routinely removed as are coverings of some surgically placed central venous catheters. Stabilization sutures are not routinely placed during this procedure. Occasionally a small amount of bleeding occurs at the insertion site; this generally stops spontaneously or with gentle pressure. With the three-way stopcock in place, central venous pressure measurement and infusion of medications, IV fluids, and hyperalimentation solutions can be performed.

**Complications**

The incidence of complications from central venous catheterization ranges from 10% to 50%. [65] [68] [69] [70] Infection and thrombosis are the major risks associated with these catheters. [53] [71] [72] Other complications include accidental displacement, phlebitis, hemorrhage, hematoma, dysrhythmia, air embolus, vascular obstruction or perforation, right atrial perforation, and localized edema. Blood sampling from indwelling central venous lines must be performed with caution, because the risk of contamination increases each time the system is opened. Morbidity from complications can be minimized by removing catheters as soon as they are no longer needed. Occasionally infections associated with central venous lines can be successfully treated with antibiotics alone. In the majority of catheter-associated infections, however, the catheters must be removed to resolve the infection. Colonization of the catheter tip is related to in situ time, younger age, and inotropic support. [73] Central venous catheters are generally free of colonization if used for no more than 3 days in infants under 1 year and no more than 6 days in older children. Right atrial and major vessel thrombus formation can be monitored using echocardiography; treatment with fibrinolytic agents is occasionally successful in restoring catheter patency. [74] These types of catheters have been used for up to 80 days, with a mean duration as long as 34 days, in very-low-birth-weight neonates. [53] [55] Most clinicians find that the majority of these catheters are discontinued because they are no longer needed. [49]

**Emergency Vascular Access**

The first steps in managing pediatric resuscitations are to establish an adequate airway, ensure adequate ventilation, and enhance blood circulation. Maintaining or reestablishing adequate circulation often requires prompt access to the intravascular space for administration of fluids and/or medications. The difficulty of obtaining venous access during pediatric resuscitations can be considerable. [75] [76] In the review by Rossetti and colleagues, IV access required 10 or more minutes in 24% of the cases. Only 6% of cases had no IV line established before attempts at resuscitation were halted. The average time required for a cutdown was 24 minutes. Children who were successfully resuscitated had vascular access achieved significantly sooner than those who were not resuscitated. Emergency IV access was most prolonged in children <2 years of age. [75] This last finding is important, since the majority of cardiopulmonary arrests in children occur in this younger age group.

If no IV line is available, appropriate drugs can be given via the endotracheal tube (see Chapter 27) while attempts at venous access are initiated. *The initial attempts at venous access should consist of peripheral placement by percutaneous venipuncture*; however, if such placement is unsuccessful within the first 1 to 2 minutes, an IO line should be started in children <6 years of age, and percutaneous central venous cannulation or saphenous venous cutdown should be performed in children older than 6 years of age. [64] The femoral vein is often the central vein of choice in emergencies, because its consistent anatomic location and large size make it the safest and easiest central vein to catheterize. The femoral vein also can be accessed with minimal interference to resuscitative efforts. However, pulsations may be present in the vein during CPR, thus

making the distinction between femoral vein and femoral artery challenging. [58]

An IV protocol for resuscitations helps eliminate the common mistake of persisting with futile attempts at peripheral sites and wasting precious time (Fig. 18-18) (Figure Not Available) . [54] If experienced personnel are available, a simultaneous cutdown of the greater saphenous vein at the ankle or the groin can be performed. One advantage of a cutdown at the groin level is that the saphenous vein can be cannulated and a double-lumen catheter advanced into the femoral vein for rapid fluid infusions through one port and medication administration through the other port. Depending on the experience of the physicians involved in the resuscitation effort, a subclavian or internal jugular catheter insertion may be attempted; however, these are not easy procedures, and attempts may interfere with chest compressions and securing of the airway. One group reported a 92% success rate with percutaneous subclavian vein catheterization in critically ill infants using a Seldinger technique. [63]

## Umbilical Vein Catheterization

### Indications and Contraindications

The major indication for umbilical vein catheterization is access to the vascular system for emergency resuscitation

**Figure 18-18** *(Figure Not Available)* Priorities for emergency vascular access in infants and children. *(From Textbook of Pediatric Advanced Life Support, 1994. Reproduced with permission. Copyright American Heart Association.)*

and stabilization of the newborn. The umbilical vein may also be used for exchange transfusions and short-term central venous access in newborns. The umbilical vein may be cannulated up to the age of 5 to 7 days, but after 1 week of life, the technique is not generally used. The procedure is technically easier than umbilical artery cannulation. *Umbilical vein catheterization is not an acceptable alternative after the infant leaves the hospital*; for example, the procedure would not be used when a 2- to 4-week-old infant presents to the emergency department.

### Equipment and Setup

The supplies and equipment for catheterization are listed in Table 18-5 . Although unlikely to be needed for most emergency

**TABLE 18-5** -- Umbilical Vein and Artery Catheterization Equipment

Infusion solution (usually D5-10 W with electrolytes. Some physicians also add 1 unit heparin per milliliter of fluid to "prevent" clotting in the catheter) Fluid chamber, IV tubing, infusion pump, filter (0.22 mum), short length of IV tubing, three-way stopcock
Umbilical artery catheter (3.5 to 5 Fr)
3-0 silk suture on a curved needle
Curved iris forceps without teeth
Small clamps, forceps, scissors, needle holder
Sterile drapes
Light source
10 mL of heparinized solution for flush (1 to 2 units heparin per milliliter of fluid)
Surgical cap, mask, gown, and gloves

department resuscitations, double-lumen umbilical venous catheters (#C-DUCO 5.0-30, Cook Critical Care, Bloomington, IN) are available that minimize the need for multiple venous catheters in the infant. [77] The infant is placed beneath a radiant warmer, and the extremities are restrained. Oxygen is administered as needed, and the audible beep on the cardiac monitor is turned on. The operator should wear a surgical cap and mask and a sterile gown and gloves.

**Technique**

The infant's extremities are restrained using gauze wrapped around the ankles and wrist and pinned to the bed. An assistant is used to hold the umbilical stump up. The cord is scrubbed with a bactericidal solution. Pooling of liquid at the infant's side should be avoided, because this may be associated with blistering of the skin under a radiant warmer. The umbilical area is draped in a sterile fashion, with the infant's head left exposed for observation.

To provide hemostasis and to anchor the line after placement, a pursestring suture is placed at the junction of the skin and the cord (Fig. 18-19) . Alternatively, a constricting loop of umbilical tape in the same position may be used. The cord is cut about 1 cm from the skin, and the vessels are identified. The vein is usually located at 12 o'clock and has a thin wall and large lumen and may continue to bleed after cutting, whereas the two arteries have thicker walls and smaller lumina, and constriction prevents bleeding after being cut. Occasionally a persistent urachus may be mistaken for the umbilical vein, but the return of urine should identify the mistake.

The catheter (3.5 Fr [preterm infants] to 5.0 Fr [term infants]), which has been flushed with heparinized saline

**Figure 18-19** When placing an umbilical vein catheter, a pursestring suture or umbilical tape is passed around the base of the cord to provide hemostasis and to anchor the line.

and attached to a three-way stopcock, is placed in the lumen of the umbilical vein and advanced gently. The catheter is advanced only 1 to 2 cm beyond the point at which good blood return is obtained. This is usually only 4 to 5 cm in a term-sized infant. If the catheter is pushed farther than this, it will do one of two things: It may enter the ductus venosus and then move into the inferior vena cava, or it may enter a branch of the portal vein within the liver (evidenced by resistance at 5 to 10 cm).

The *inferior vena caval site* may be a desirable location in some newborn infants in whom peripheral vascular access is limited and for whom central venous access is desired for central venous pressure monitoring or infusion of medications, high concentrations of glucose (>10%), IV fluids, and hyperalimentation solutions. The catheter must be inserted approximately 10 to 12 cm in a term-sized infant to reach the inferior vena cava. The *portal vein site* can be verified by radiographs that document the placement of the catheter. Note that an umbilical venous catheter will proceed directly cephalad (without making a downward loop) until it passes through the ductus venosus (Fig. 18-20) (Figure Not Available) . Of course, in a resuscitation, radiographic documentation may not be possible. Therefore, it is generally recommended that the catheter be inserted approximately 4 to 5 cm to minimize the risk of injecting sclerosing solutions into the liver.

Air embolism may occur at the time of catheter removal if the infant generates sufficient negative intrathoracic pressure (as during crying) to cause air to be drawn into the patent umbilical vein. Therefore, caution must be used during catheter removal to ensure that the vein is promptly occluded (by tightening a pursestring suture or applying pressure on or just cephalad to the umbilicus).

### Complications

Complications of umbilical venous catheters include hemorrhage, infection, injection of sclerosing substances into the liver (resulting in hepatic necrosis), air embolism, and vessel perforation. It is most important that one follow careful technique in insertion and maintenance of catheters to minimize such complications.

## Umbilical Artery Catheterization

### Indications and Contraindications

Umbilical artery catheterization is a useful procedure in the care of newborn infants who require frequent monitoring of arterial blood gases and arterial blood pressure, fluid and medication administration, and exchange transfusions. It is imperative for the clinician to remain aware of potential complications. [78] [79] [80] One of the two umbilical arteries may be cannulated for resuscitation purposes, but an umbilical vein is generally technically easier to cannulate and may be preferred in an emergency.

### Equipment and Setup

The equipment required for umbilical artery catheterization is identical to that used for umbilical venous catheterization. Additional equipment needed for continuous arterial pressure monitoring and infusion should be readily available.

**Technique**

The technique of umbilical artery catheterization is similar to that described for umbilical vein catheterization in the preceding section. After the umbilical arteries have been located, the cord is grasped with a curved hemostat near the selected artery (Fig. 18-21) . This maneuver is important, because it provides clear visualization and stabilization of the vessel. Using the curved iris forceps without teeth, one gently dilates the artery. Umbilical artery spasm may make the procedure difficult. A 3.5 to 5 Fr catheter is attached to a three-way stopcock and is flushed with sterile heparinized solution. The catheter may then be introduced into the dilated artery. A 3.5 to 4 Fr catheter is recommended for infants weighing <2 kg and a 5 Fr catheter for those weighing 2 kg.

When the catheter is being inserted, tension should be placed cephalad on the cord, and the catheter should be advanced with slow, constant pressure toward the feet (Fig. 18-22) . Resistance is occasionally felt at 1 to 2 cm and should be overcome by gentle, sustained pressure. If the

**Figure 18-20** (Figure Not Available) An umbilical vein catheter is directed toward the head and remains anterior until it passes through the ductus venosus into the inferior vena cava. *(From Ludwig S, Fleisher GR: Textbook of Pediatric Emergency Medicine. Baltimore, Williams & Wilkins, 1994.)*

**Figure 18-21** The umbilical cord is grasped with a curved hemostat near the selected artery. The umbilical artery is then dilated with curved iris forceps.

catheter passes 4 to 5 cm and meets resistance, this generally indicates that a "false passage" through the vessel wall has occurred. Occasionally one may bypass the perforation by attempting catheterization with the larger 5 Fr catheter.

The optimal position of the catheter tip in the descending aorta remains the subject of much debate. [81] [82] [83] If a low (L3 to L4) position is desired, the catheter may be advanced 7 to 8 cm in a 1-kg premature infant or 12 to 13 cm in a full-term infant. Graphs are available to estimate the proper length of insertion for a high or low catheter location. [84] [85] Once sterile technique is broken, the line may not be advanced. It is therefore preferable to position the catheter too high and to withdraw as necessary according to the location on a radiograph. After it has been positioned appropriately, the catheter should be tied with the previously placed suture (Fig. 18-23) and taped to the abdominal wall. A radiograph should be obtained and the catheter repositioned, if necessary, with the tip at the lower border of the L3 vertebra. Some clinicians prefer to place the catheter high (T6 to T9 vertebrae). There are no unequivocal data to support either preference. [86] [87]

Radiographs of an arterial catheter (Fig. 18-24) will show the catheter proceeding from the umbilicus down toward the pelvis, making an acute turn into the internal iliac artery, continuing toward the head into the bifurcation of the aorta, and then moving up the aorta slightly to the left of the vertebral column. [88]

Most unsuccessful umbilical artery catheterization attempts fail because the catheter perforates the arterial wall approximately 1 cm below the umbilical stump, where the umbilical artery begins curving toward the feet. [89] In this instance, the catheter is advanced in the extraluminal space, and resistance is met at 4 to 6 cm. The following maneuvers make it possible to avoid perforating the umbilical arterial wall in most cases:

1. The catheter should be advanced slowly. When slight resistance is met at approximately 1 cm, the catheter should be advanced very gently with steady pressure. It should never be forced, because it will likely perforate the wall. A catheter or feeding tube with a molded tip should be used. A catheter tip that has been cut with scissors is more difficult to insert and advance.
2. Because the artery curves toward the feet, the umbilical stump should be held with a curved clamp and should be pulled toward the head so that the catheter is inserted toward the feet in as straight a direction as possible.

The use of a placenta or a commercially available simulator

**Figure 18-22** The catheter is introduced into the dilated artery and advanced toward the feet. The suture placed around the base of the cord is tied to the catheter.

**Figure 18-23** The tape is pleated above and below the catheter.

(Medical Plastics Laboratory, Gatesville, Tex) makes it relatively easy to demonstrate and practice the proper technique of umbilical artery catheterization. [90] [91]

**Complications**

If the catheter becomes plugged or fails to function properly or if there is blanching or discoloration of the buttocks, the heels, or the toes, then the catheter should be removed at once. Umbilical arteries are most easily cannulated in the first few hours of life but may provide a viable vascular route as late as 5 to 7 days of age.

Complications include hemorrhage, [92] infection, [93] [94] [95] thromboembolic phenomena (especially to the kidneys, the gastrointestinal tract, and the lower extremities), [96] [97] [98] aortic thrombosis, [99] aortic aneurysm, [100] vasospasm, air embolism, vessel perforation, peritoneal perforation, hypertension, [101] [102] and possible effects of plasticizers. [103]

## Percutaneous Arterial Catheterization

### Indications and Contraindications

Despite the growing use of noninvasive devices for monitoring transcutaneous oxygen and carbon dioxide, percutaneous

**Figure 18-24** The umbilical artery catheter makes a loop downward before heading cephalad (schematic drawing of a radiograph interpretation).

peripheral arterial catheterization is indicated when there is a need for frequent blood gas sampling, continuous arterial blood pressure monitoring, or both. Arteries used for peripheral catheters in infants include the radial, [104] ulnar, [105] femoral, [106] temporal, [107] [108] and posterior tibial arteries. [109]

Percutaneous radial artery catheterization has become widely accepted and has been shown to be a safe method in infants and children. [110] The catheter allows for preductal blood gas determinations if placed in the right radial artery. Only the procedure for radial artery catheterization is described here, but catheterization of other vessels is similar.

The following are contraindications to peripheral arterial catheterization:

> Situations in which adequate peripheral arterial samples can be obtained by percutaneous punctures

> Situations in which circulation of the extremity to be catheterized is compromised

> Situations in which occlusion of the vessel to be catheterized results in compromised perfusion of that extremity

> The presence of an ongoing bleeding diathesis

> The presence of localized infection or inflammation overlying the artery to be cannulated

> Situations in which intensive monitoring of line function is not available.

### Equipment and Setup

The equipment needed for arterial catheterization is essentially the same as that required for percutaneous peripheral venous catheterization (see Table 18-4) . The catheters used are usually 22- or 24-ga over-the-needle catheters, a T-piece connector, and a stopcock. One should connect the T piece and the stopcock and then fill them with normal saline solution. An infusion pump with heparinized saline (1 to 5 U/mL)

should be readied. [111]

**Technique**

The procedure should be performed with good lighting and an adequate work area, with the infant's heart and respiratory rates monitored closely. The radial artery may be palpated proximally to the transverse wrist crease on the palmar surface of the wrist, medial to the styloid process of the radius. The artery is then compressed, and the hand and

fingers are observed for color change. If blanching or cyanosis is noted (indicating poor collateral circulation), catheterization is not performed.

A fiberoptic transilluminator may be used to localize the artery. With the overhead lights off, the transilluminator head (with a rubber shield or filter to prevent overheating the skin) is positioned beneath the wrist, and the artery is visualized as a dark, pulsatile shadow. [112] [113]

The infant or child's hand and lower forearm are secured to an arm board with the wrist dorsiflexed 45° to 60° with the aid of a roll of gauze placed underneath. Care must be taken to leave the fingers exposed to assess the peripheral circulation. The radial artery is palpated at the point of maximal impulse and can be marked with a gentle indentation by one's fingernail. The area over the radial artery is prepared with a povidone-iodine solution and washed with alcohol. A local anesthetic such as 1% lidocaine without epinephrine may be used at the planned insertion site. The catheter with stylet is inserted through the skin just proximal to the transverse wrist crease at a 10° to 20° angle (Fig. 18-25) . The catheter with needle is advanced slowly until blood appears in the catheter hub, signifying puncture of the anterior arterial wall. The catheter is slowly advanced further until blood appears in the needle and then the needle angle is carefully lowered to approximately 10°. The catheter is slowly advanced over the needle into the lumen of the artery, and the needle is removed. The stopcock and T-piece connector are attached to the catheter hub. The stopcock is opened to the syringe to confirm pulsatile blood return. It is then flushed with 0.5 mL heparinized flush solution very gently to clear the catheter while the fingers and the hand are observed for evidence of blanching or cyanosis.

The puncture site is then covered with antibiotic ointment, and the catheter is fixed to the skin by a thin piece of tape placed adhesive side uppermost under the catheter hub and crossed over the catheter in a V shape. A second piece of tape is passed around and over the catheter hub and is fixed to the wrist (Fig. 18-26) . A small piece of tape is used to attach the T-piece connector to the wrist area or to the splint. The fingers should be easily visible.

Only heparinized normal or half-normal saline is used for infusion. Some clinicians prefer to add 1 to 5 U of

**Figure 18-25** The catheter assembly is introduced into the radial artery through skin at a 10° to 20° angle.

**Figure 18-26** One technique of taping the arterial catheter. The arm board should be well padded and secured.

heparin per milliliter of infusion solution infused at a rate of 1 to 2 mL/hour. Medications, blood or blood products, amino acid solutions, IV fat solutions, and hypertonic solutions are not infused through the catheter.

The catheter must be removed when there is evidence of blanching or cyanosis or when it is impossible to withdraw blood from the catheter or difficult to flush the catheter.

**Complications**

Complications, which have been reported with every type of arterial catheter, include hemorrhage, thrombosis, spasm, infection, scars, air embolism, retrograde blood flow, transient elevation in blood pressure with rapid (<1 second) infusion, and nerve damage. Thrombosis or spasm may result in blanching or cyanosis of the extremity or skin. [114] [115] [116] There is potential for loss of digits, an entire extremity, or large areas of skin, as well as cerebral infarction with temporal artery catheters. [117] [118] [119] Malposition of the catheter such that infusion of a glucose solution flows into the celiac artery may also precipitate hypoglycemia on discontinuation of the glucose infusion. Saladino and colleagues note that complications from emergency department-placed arterial lines are uncommon and generally minor. [120]

**Figure 18-27** Anatomy of the posterior tibial artery and surrounding structures.

**Figure 18-28** Posterior tibial artery cutdown technique. With the foot prepared and immobilized, a 5- to 7-mm incision is made in the skin posterior to and at the midline of the medial malleolus. Curved forceps and a silk suture are inserted beneath the posterior tibial artery, which courses just posterior to the medial malleolus.

## Arterial Cutdown Catheterization

### Indications and Contraindications

Arterial catheterization by cutdown on the posterior tibial artery, radial artery, and temporal artery may be indicated when the need exists for frequent monitoring of arterial blood gases or blood pressure and when percutaneous access is not possible. [109] [121] Arterial cutdowns are contraindicated when (1) adequate peripheral blood gas samples can be obtained by percutaneous punctures or catheterization, (2) circulation of the extremity to be catheterized is compromised, or (3) occlusion of the vessel to be catheterized results in compromised perfusion of that extremity.

**Equipment and Setup**

Successful arterial cutdown catheterization in the small infant requires sterile instruments, an assistant, good lighting, and a selection of catheters. Previous clinical experience is helpful. The use of self-retaining retractors is a personal preference. Because of temperature instability, a warming light or an overhead radiant warmer is frequently useful. The equipment required for performing an arterial cutdown catheterization can be found on a cutdown tray, available in most emergency departments. Also needed are a 22- or 24-ga over-the-needle catheter, T-extension connector tubing, stopcock, a 5- or 10-mL syringe filled with flush solution (normal saline with 1 to 5 U heparin/mL) and silk suture ties.

**Technique**

The anatomy and technique for posterior tibial arterial cutdown are described in detail (Fig. 18-27) . The same technique is applicable for the radial artery. The clinician stabilizes the foot in a neutral position by taping the externally rotated lower leg to a splint. The *posterior* tibial artery is then localized by Doppler ultrasound just posterior to the medial malleolus. The operator prepares for the procedure by scrubbing and donning a gown and gloves; the foot is prepared with a povidone-iodine solution.

Following SQ injection of 1% lidocaine, a 5- to 7-mm transverse incision is made in the skin over the artery posterior to and at the midlevel of the medial malleolus (Fig. 18-28) . Using blunt dissection in a vertical direction (parallel to the vessels), the tissue is separated with a small, curved forceps, and the artery is identified. The artery courses with the vein just anterior and superficial to the nerve and is usually pulsatile. One isolates the artery by sliding a small, curved forceps beneath it and gently elevating the vessel (see Fig. 18-28) . Excessive manipulation of the artery can cause spasm; if this occurs, a few drops of 1% lidocaine applied locally may result in dilation. A silk tie (without a needle) is then placed beneath the artery to stabilize it during cannulation.

**Figure 18-29** Technique of inserting the arterial catheter. A silk tie is used *only to stabilize the artery during cannulation*. It is never tied. The catheter is inserted under direct vision without making an incision in the vessel.

**Figure 18-30** The skin incision is closed, and the catheter and connector are secured to the heel with tape.

At a 10° angle, a 22-ga Angiocath with the catheter bevel down is inserted into the artery over the surface of the forceps. When blood return is seen, the catheter is advanced over the stylet to its full length (Fig. 18-29) . The needle stylet is then removed, and the catheter is connected to the T-connector tubing and a three-way stopcock that has been prefilled with heparinized flush solution. Patency is checked by observation of blood return with pulsations; the catheter is then flushed slowly and gently. The silk suture is removed, and the skin incision is sutured. The catheter is

sutured to the skin over the heel. The catheter and connector are then secured to the heel with tape (Fig. 18-30) . The stopcock is then connected to the infusion line.

**Complications**

The complications of arterial cutdown are similar to those of percutaneous arterial catheterization. They include hemorrhage, thrombosis, or spasm resulting in loss of tissue; infections; permanent scars; and nerve damage. Complications have been reported with all types of arterial cutdown. Follow-up data and computed tomography data suggest an association between temporal artery catheterization by the cutdown technique and cerebral infarct that may result in hemiparesis. [122] Therefore, temporal artery catheterization should be the last choice for arterial catheterization.

# Chapter 19 - Arterial Puncture and Cannulation

**William J. Barker**

Arterial blood gas evaluation provides useful information that is essentially unavailable by other means. The respiratory status and acid-base equilibrium of individuals with pulmonary disorders, drug overdoses, and metabolic diseases may be evaluated through this procedure. The current sophistication of critical care medicine would be impossible without arterial access, permitting continuous arterial pressure monitoring and frequent blood sampling for metabolic and hematologic indices.

Currently access to the arterial system can be easily obtained in most patients. Many improvements in arterial access methodology and equipment have occurred since Hales, in 1733, first used a technique similar to today's cutdown technique to attach a fluid column for measurement of the blood pressure of a horse. [1] J. L. M. Poiseuille first introduced the use of a mercury manometer for the measurement of blood pressure in 1828. In 1847, Karl Ludwig graphically recorded blood pressure fluctuations by placing a float with a pointer on the mercury column, permitting the pointer to scratch a smoked drum rotating adjacent to the column. Today's manometers, transducers, and recorders use electronics rather than simple mechanics, thus permitting mathematical waveform analysis in addition to visual analysis.

## INDICATIONS AND CONTRAINDICATIONS

Many patients who are seen in the emergency department benefit from arterial puncture or cannulation (Table 19-1) . Most commonly, arterial blood gases are used to evaluate individuals who have significant respiratory pathology. Although most patients with respiratory illness may be managed without arterial puncture, arterial blood gas determination is imperative when they are severely ill. Critically ill patients with nonrespiratory disease may need frequent metabolic and electrolyte monitoring. For instance, the patient with severe diabetic ketoacidosis cannot be managed properly without frequent pH, electrolyte, and glucose measurements.

| TABLE 19-1 -- Arterial Puncture and Cannulation | |
| --- | --- |
| **Indications** | **Relative Contraindications** |

| | |
|---|---|
| Blood gas sampling | Previous surgery in the area, especially cutdown |
| Continuous pressure monitoring | |
| Frequent blood sampling for any purpose | Anticoagulation |
| | Coagulopathy |
| Diagnostic angiography | Skin infection at site |
| Therapeutic embolization | Atherosclerosis |
| | Decreased collateral flow |

Although arterial blood gas analysis is the most frequent indication for arterial puncture, all blood chemistry tests can be performed from an arterial sample. Blood cultures may also be obtained through an indwelling arterial line, with sensitivity and specificity equal to those of cultures obtained from a venipuncture site. [2] [3] When frequent blood sampling is required, it is easier and certainly more humane to insert an indwelling arterial cannula. The nurse who is caring for the patient may then sample the blood as needed.

The most common indication for long-term arterial cannulation is continuous monitoring of arterial blood pressure. An electromechanical pressure transducer attached to an oscilloscope screen allows continuous observation of arterial systolic and diastolic pressures. This capability is most useful in a critical care unit but is also helpful when available in an emergency department. Many situations, such as the use of vasoactive drugs (e.g., nitroprusside and dopamine), require continuous arterial pressure monitoring. The response of trauma and cardiac patients to resuscitative efforts also may be more easily followed in this manner.

Another common use of arterial puncture is radiologic diagnostic imaging of the arterial system. Obviously this is an uncommon indication in the emergency department, but it

may be considered for suspected cases of peripheral arterial trauma or embolism. Although this procedure is fairly simple to perform, arterial access for diagnostic imaging is most often performed by a radiologist. Arterial puncture is also used by cardiologists and radiologists for coronary, cerebral, renal, and other central arterial angiography. Aortography can be very important for chest trauma and suspected cases of dissecting or leaking aneurysms.

Few contraindications to arterial puncture exist; none are absolute. Arterial puncture performed in patients who are anticoagulated or who have other coagulopathies should be undertaken with extreme care. Luce and associates reported 7 patients with compression neuropathies secondary to hematoma after arterial puncture, all of whom were anticoagulated at the time of puncture. [4] Repeated arterial sampling in these patients may necessitate insertion of an indwelling cannula to minimize the number of puncture sites in the arterial wall. Arterial cannulation or puncture should be used in a patient receiving thrombolytic therapy *only* if it will provide essential data that cannot be obtained in any other fashion.

The presence of severe atherosclerosis, with or without diminution of flow, is a relative contraindication to arterial puncture, especially when followed by cannulation. The existence of a bruit or a palpable decrease in the pulse should warn the physician of the presence of intravascular disease. If either is noted and the arterial puncture is imperative, an alternative site should be considered.

Evidence of decreased or absent collateral flow in areas in which flow normally exists should also lead one to consider an alternative site. A positive Allen test (discussed in Techniques) may possibly eliminate the radial and ulnar arteries as sites of cannulation. One should also avoid puncture of an artery when infection, burn, or other damage to cutaneous defenses exists in the overlying skin.

## EQUIPMENT

The equipment used for arterial cannulation has a great influence on the accuracy of pressure measurements. The frequency responses of tubing, transducers, and other components of the monitoring system influence the measurement accuracy of systolic and diastolic pressures.

The dynamic response characteristics of the monitoring system are of minimal importance if the clinician is interested primarily in the mean arterial pressure (MAP). [5] In the emergency department, trends in the MAP are more useful than absolute values for systolic and diastolic pressures.

The various catheter types have demonstrated similar frequency response characteristics, but studies have shown more variable effects on complication rates. Teflon catheters have been implicated as a factor associated with increased thrombosis in 1 study, [6] whereas the results of other studies deny any such effect. [7] [8] [9] The diameter of the indwelling cannula seems to have a more consistent effect; the incidence of thrombosis is inversely related to the ratio of vessel lumen to catheter diameter. [10] Thus, for a given vessel size, the incidence of thrombosis will decrease as

the catheter diameter decreases. Catheter choice should be influenced by availability and convenience of use of a particular brand. A short catheter is ideal for peripheral artery cannulation, whereas a longer over-the-needle catheter is preferable for the femoral artery (Fig. 19-1) . Downs and associates suggest that thrombosis is less likely with a nontapered catheter. [11] An 18- to 20-ga catheter should be used in adults. Small children and infants require a 22- to 24-ga catheter, which may need to be inserted through a cutdown technique.

The tubing that connects the catheter to the pressure transducer has a significant effect on monitoring systems. The higher the frequency response of the entire system, the more accurate the determination of systolic and diastolic pressure. [5] [12] A stiff, low-capacitance plastic tubing should be used, and the manometer should be placed as close as possible to the patient, because the frequency response of a tube is inversely related to its length. [12] [13] [14]

After the pressure wave is transmitted from the artery through the catheter and connecting tubing, a measuring device is required to obtain a numerical value for the arterial pressure. Currently the most commonly used device is an electromechanical pressure transducer that changes a mechanical pressure pulse, the fluid wave, into an electrical

**Figure 19-1** Catheters that may be used for arterial line insertion. Short, small-gauge over-the-needle catheters are ideal for peripheral artery cannulation *(top)*. The long over-the-needle catheter is used for femoral arterial lines *(bottom)*.

**Figure 19-2** (Figure Not Available) Assembly technique for anaeroid manometer system. The middle and proximal extension tubings contain heparinized saline. The middle extension tubing is arranged to form a fluid meniscus at the same level as the heart when the proximal stopcock is closed to the middle tubing (i.e., no pressure input). The distal extension tubing is filled with air and held vertically so that there is no saline contamination of the manometer at maximal pressures. Approximately 10 to 12 cm of air in the distal and middle tubings is optimal. The same system can be used with a mercury manometer in place of the anaeroid manometer. Sterility of the extension tubing and stopcocks is essential. (From Zorab JSM: Continuous display of the arterial pressure: A simple manometric technique. Anaesthesia 24:433, 1969. Copyright © 1969 by the Association of Anaesthetists of Great Britain and Ireland. Reproduced by permission.)

signal, which is then displayed on an oscilloscope. Additional circuitry can be added to display the systolic and diastolic pressure as numerical values. Various minicomputer systems that allow computation of mean arterial pressure, trend monitoring, and other capabilities in addition to displaying the systolic and diastolic pressures are available. So many transducer and oscilloscope combinations exist that a discussion of their relative merits is beyond the scope of this chapter.

Intravascular transducers are also available but have many potential disadvantages and are used infrequently. They are fragile, temperature sensitive, of variable quality, and much more difficult to place into a vessel than is a catheter. Fibrin deposition on the device is also a common finding. The greatest, and possibly only, advantage of these intravascular transducers is the elimination of potential error induced by catheters,

stopcocks, and connecting tubing.

Less expensive means of deriving a number representative of the arterial pressure are available, especially if one is interested in determining only the mean arterial pressure (MAP). Zorab describes the use of an anaeroid manometer connected to the arterial system by a catheter filled with heparinized saline. [15] The catheter is arranged to have a fluid meniscus at the same level as the heart when there is no pressure input. The meniscus is below an air column in a vertical tube that is long enough to avoid saline contamination of the manometer at maximal pressures (Fig. 19-2) (Figure Not Available) . A mercury manometer, especially a J tube, may also be used in place of an anaeroid manometer in the previously described system for measurement of MAP.

For continuous arterial pressure monitoring, some method of flushing the system is necessary to maintain patency of the catheter lumen. This may be as simple as a three-way stopcock through which the tubing is intermittently flushed with heparinized saline. There are continuous flush devices that are designed to push a set amount of fluid (usually 2 to 3 mL/hour) through the line. A typical monitoring system that includes this device is shown in Figure 19-3 (Figure Not Available) . The pressure transducer is usually mounted at the level of the patient's heart on a bedside pole.

**Figure 19-3** (Figure Not Available) Arterial pressure monitoring systems. *A,* System for continuous flush. Heparin (2 mL of a 1:1000 unit solution) is added to a 1-L bag of normal saline, and the bag is pressurized to 300 mm Hg using a metered blood pump (not shown). The continuous flush device is set to deliver 3 mL/hour of the heparinized saline. A mechanical pressure transducer (Pressurveil, Concept Co.) is depicted. The transducer device is a sterile, inexpensive, fully assembled monitor that can be used during patient transfer. Alternatively, the electronic transducer depicted in *B* may be used. *B,* System for manual flush. A heparinized saline flush solution can be injected manually through a syringe at the proximal or distal port. The transducer dome should be maintained at the level of the patient's heart. (From Beal JM [ed]: Critical Care for Surgical Patients. New York, Macmillan, 1982. Reproduced by permission.)

**Figure 19-4** Arterial blood gas kit. Contents include skin preparation pads, prefilled heparinized syringe, stopper for syringe, needles, gauze sponges, and plastic bag for crushed ice.

The equipment needed to percutaneously obtain a single sample for arterial blood gas analysis is simple and readily available in any hospital, often in the form of a prepackaged kit (Fig. 19-4) . The necessary items for arterial line placement are listed in Table 19-2 and referred to in the section that describes the procedures. Obtaining a sample from an indwelling arterial line requires only 2 syringes, 1 of which has been heparinized.

## SITE SELECTION

Selection of an arterial site is the first step in placing an indwelling cannula or obtaining a sample of arterial blood for a blood gas analysis. Successful cannulation of the radial, ulnar, brachial, axillary, dorsalis pedis, and femoral arteries in children and adults is possible. The temporal and umbilical arteries are often cannulated in infants and

neonates. However,

| Forceps |

radial artery cannulation is also very safe for these patients [16] (see Chapter 18) . The radial, brachial, and femoral arteries are usually punctured for blood gas sampling in adults.

The potential consequence of total loss of blood flow through a vessel due to

intraluminal thrombosis is one of several variables that must be considered when choosing a site for arterial puncture. Arteries known to have good collateral blood flow, such as the radial and dorsalis pedis, are thus favored. Determining the effect of the site chosen on the ease of patient care will be appreciated by those who will subsequently be providing that care. An arterial line in the lower extremities may be preferred during a procedure on the upper body, whereas a femoral or axillary line may be poorly tolerated by patients who are capable of positioning themselves. Characteristics of the common arterial sites are discussed following general descriptions of the techniques of arterial puncture and cannulation.

## TECHNIQUES

### Percutaneous Technique for Single Arterial Puncture

To obtain a single sample of arterial blood by the percutaneous method, a small (5-mL) syringe is attached to a 20- to 22-ga needle. A smaller needle may be required for young children or individuals who have had many previous punctures. To prevent clotting of the sample, 1 or 2 mL of a heparinized saline solution (1000 IU/mL) are drawn into the syringe to coat the barrel and needle and are then ejected through the needle shortly before puncture. All of the visible heparin is ejected, so that all that remains is enough anticoagulant to coat the barrel and fill the dead space of the syringe and needle, minimizing heparin-related errors.

Because of the air-fluid boundary in the heparin storage bottle, heparin solution has a higher $P_{O2}$ and a lower $P_{CO2}$ than blood, and changes in these parameters reflect a dilutional effect. The addition of 0.4 mL of heparin solution to a 2-mL sample of blood (dilution of 20%) will lower the $P_{CO2}$ by 16%. A falsely low $P_{CO2}$ is the most clinically significant change caused by excess heparin. [17] [18] $P_{O2}$ levels are not significantly altered by the addition of heparin in most instances, although a slight increase in $P_{O2}$ has been reported. The pH is affected (lowered) only if high concentrations of heparin are used (25,000 IU/mL), but generally the tremendous buffering capacity of blood maintains a normal pH. The dead space of a 5-mL Luer-Lok glass syringe and a 22-ga, 3.8-cm needle is 0.2 mL. Therefore, to minimize heparin-related error, *at least 3 mL of blood should be collected*, even though blood gas analysis equipment requires only a 0.5-mL sample. Some packaged blood gas syringes contain a powdered heparin that mixes with the arterial blood. Although thrombosis of the needle may be more common with this system, smaller volumes (1 mL) of blood can be used.

The arterial pulse is palpated to ascertain the location of the vessel, and the overlying skin is prepared sterilely with an iodophor or other antiseptic solution. The patient's skin should then be anesthetized with a wheal of local anesthetic without epinephrine placed through a small-gauge (25- or 27-ga) needle. If the patient is unresponsive to pain in the

**Figure 19-5** Arterial puncture at the wrist. The index and middle fingers are used to isolate and outline the course of the pulsating artery before insertion of the needle. Contrary to the illustration, latex gloves should be worn during the procedure.

area, this step may be omitted. Care must be taken to use a small amount of local anesthetic, because a large wheal may obscure the pulse.

The arterial pulsation is then isolated between the index and middle fingers of the *gloved* nondominant hand (Fig. 19-5) . The skin should be punctured through the anesthetic wheal, and the needle should be advanced toward the pulsating vessel. The needle should form an angle of about 15° to 20° with the skin. A larger angle is required for femoral artery puncture. Once the needle has entered the arterial lumen, the syringe plunger should be allowed to rise with the arterial pressure to minimize the chance of venous sampling. If no blood flow is obtained, the needle should be withdrawn slowly, because both walls of the vessel may have been punctured. A sample may be obtained during withdrawal. Redirection of the needle should occur only when the needle has been retracted to a location just deep to the dermis.

Maher and Dougherty describe the use of a hand-held Doppler ultrasound probe to aid arterial puncture. [19] The probe is held over the artery proximal to the puncture site. Loss of audible pulsations suggests vessel compression with imminent arterial puncture.

After a sample of at least 3 mL of blood has been obtained, the needle is removed from the artery, and firm pressure is applied at the puncture site for a minimum of 5 minutes. Ten to 15 minutes of pressure is required if the patient is on anticoagulant therapy or has a coagulopathy.

Proper handling of the sample is very important. When the needle is withdrawn, it is imperative to expel any air bubbles that are present in the syringe to avoid false elevation of the $P_{O2}$ . [20] Air in the sample will significantly increase the $P_{O2}$ (mean increase, 11 mm Hg) after 20 minutes of storage, even if kept at 4 °C. The pH and $P_{CO2}$ are not significantly altered by air bubbles if the blood is stored at 4 °C for 20 minutes.

Removal of air is neatly and easily accomplished by placing an alcohol wipe or gauze sponge on the needle and tapping the inverted syringe to force any air to the top. Air is then pushed out of the needle, and any blood that is spilled will be caught by the sponge (Fig. 19-6) . The needle is then plugged or removed, and the syringe is capped to ensure anaerobic conditions. Blood gas analysis is ideally performed immediately, but if this is not feasible, the sample may be stored in ice water for 1 hour with limited deterioration. [20] [21] If the sample is stored anaerobically, regardless of the temperature, the $P_{O2}$ , $P_{CO2}$ , and pH are relatively stable for up to 20 minutes. If blood is stored at room temperature

**Figure 19-6** Removal of air bubbles from the syringe. *A,* Air bubbles are finger-tapped to the top of the syringe. *B,* An alcohol swab is placed over the top of the needle. *C,* The plunger is advanced to expel air while drops of blood are collected on the alcohol swab. After removal of the bubbles, the syringe is capped and sent to the laboratory.

for longer than 20 minutes, the $P_{CO2}$ will increase and the pH will decrease, probably as a result of leukocyte metabolism. In a stored sample, the $P_{O2}$ varies to such an extent

that the change is unpredictable for chemical interpretation at 30 minutes, regardless of storage method. High leukocyte or thrombocyte counts, such as those seen in leukemic patients, may shorten acceptable storage intervals. [22] [23] Local anesthesia will make the procedures of arterial puncture easier for both the patient and the physician; however, 1 study found no significant alterations in $P_{CO_2}$ or pH from the pain or anxiety of an unanesthetized arterial puncture (Table 19-3) . [24]

**Percutaneous Technique for Arterial Cannulation**

Percutaneous puncture is the preferred method for arterial cannulation. It is also the method of choice for obtaining an isolated blood gas sample (see preceding section) when an indwelling cannula has not been placed.

Once the site has been selected, the skin should be prepared with iodophor or other antiseptic solution, and sterile drapes should be placed around the area. Sterile technique should be meticulously maintained throughout the procedure. Levy and colleagues describe an alternative skin preparation method for central venous catheters that uses a 1-minute isopropyl alcohol scrub followed by catheter placement through an iodophor-impregnated adherent film (Ioban Z antimicrobial film, 3M Company, St. Paul). [25] Catheter tip and glove tip contamination were virtually eliminated. This technique may be considered for arterial cannulation as well.

The artery is entered as described in the preceding section, using a catheter-over-the needle apparatus. Once the artery has been entered, bright red blood should be visible in the flash chamber of the cannula. Advance the needle approximately 1 mm into the vessel lumen (Fig. 19-7) (Figure Not Available) , then fix the needle while threading the catheter further into the lumen. When the needle is withdrawn, blood will pulsate from the catheter hub. Inadvertent puncture of the back wall of the artery can occur, and indeed, a variation of the percutaneous technique is to puncture both walls of the

| **TABLE 19-3** -- Parameters that Affect Interpretation of Arterial Blood Gases | | | |
|---|---|---|---|
| **Parameter** | **Heparin** * | **Air Bubble in Sample** | **Delayed Analysis** |
| $P_{O_2}$ | No signficant change | Elevated | Variable ¶ |
| $P_{CO_2}$ | Lowered | No significant changes § | Elevated * |

| pH | Unchanged | No significant changes § | Lowered * |
|---|---|---|---|

* Use only 1000 IU/mL concentration; fill dead space of needle and syringe only, and collect 3 mL of blood.
Anaerobic storage at room temperature for 20 minutes results in no significant change.
There are reports of slight increases in $P_{O_2}$ with excessive heparin.

¶ Changes unpredictable at 30 minutes, regardless of storage method.
The falsely lowered $P_{CO_2}$ that occurs with added heparin is the most clinically significant change noted.
pH may be decreased if a large volume of concentrated heparin (25,000 IU/mL) is used.
§ If stored at 4° C for 20 minutes.
* *Minimal changes up to 2 hours, if stored at 4° C.

**Figure 19-7** (Figure Not Available) Percutaneous arterial cannulation at the wrist. The catheter unit is advanced 1 to 2 mm into the vessel lumen after blood first appears in the flash chamber. While the needle is fixed, the catheter is threaded over the needle. (From Beal JM [ed]: Critical Care for Surgical Patients. New York, Macmillan, 1982. Reproduced by permission.)

vessel with a single pass. If the back wall is punctured, the needle is withdrawn from the catheter, and the catheter is slowly pulled back until a steady stream of blood flows from its hub. The catheter is then advanced carefully further into the lumen. The double-puncture method is especially useful for cannulating small vessels. Jones and colleagues reported no increase in complications when both walls, rather than one, are punctured. [26]

Once the vessel has been entered, occasionally one will encounter difficulty advancing the catheter into the lumen. The "liquid stylet" method may aid further passage of the catheter. [27] A 10-mL syringe should be filled with about 5 mL of sterile normal saline. The syringe is then attached to the catheter hub, and 1 to 2 mL of blood should be easily aspirated to confirm intraluminal position. The fluid from the syringe is then slowly injected, and the catheter is advanced behind the fluid wave. Catheter sets are available with a wire stylet that permits a modified Seldinger technique for catheter placement; the over-the-needle catheter follows the self-contained guide wire during cannulation. One readily available device of this type is the Arrow arterial catheterization system (Arrow International, Inc., Reading, Pa) (Fig. 19-8) (Figure Not Available) . This device is available alone, in catheter exchange sets, and in complete single-use kits that are packaged in a container that can serve as a disposable wrist support.

Once the catheter has been placed successfully, it should be advanced until the hub is in contact with the skin. The catheter is then secured by fastening it to the skin with suture material. Silk (4-0) or nylon (5-0) sutures provide the best anchoring. To accomplish this, a moderate bite of skin is taken with the needle, and a knot is tied in the suture. Care should be taken to avoid pinching the skin too tightly. The loose ends of the suture are then tied around the catheter or its hub without occluding the lumen by constriction (Fig. 19-9) .

After tying the catheter in place, a drop of antibiotic ointment is applied to the puncture site, and a self-adhesive dressing is applied over the area. The catheter and its

connecting tubing are further secured with sterile sponges and adhesive tape. All tubing connections must be tight and secure. If the tubing becomes disconnected inadvertently, the patient may exsanguinate rapidly.

When successful arterial cannulation has been performed,

**Figure 19-8** (Figure Not Available) Step-by-step arterial cannulation, using the guide wire technique (Arrow arterial catheterization kit). (Courtesy of Arrow International, Inc., Reading, Pa.)

the catheter should be attached to a pressurized fluid-filled system. If the catheter has been placed for monitoring arterial blood pressure, it should be connected to a mechanical or electrical transducer by a short length of rigid plastic tubing filled with saline. A three-way stopcock is interposed between the patient and the transducer for blood gas sampling and to allow flushing of the system with heparinized saline (2 mL 1:1000 heparin/L of saline). Flushing

**Figure 19-9** Illustration of a technique for securing a vascular catheter to adjacent skin.

can be periodic or continuous at a rate of 3 to 4 mL/hr through a continuous flow device (see Fig. 19-3) (Figure Not Available) .

Procurement of a blood sample from this system is easily performed. A syringe is attached to the three-way stopcock, and blood is aspirated and discarded to clear the line. Studies examining the necessary discard volume of flush-blood solution have found considerable variation dependent on the volume of the system. [28] [29] Short lengths of tubing between the catheter and aspiration port minimize the discard volume. For a tubing length of 91 cm (36 in.), 4 to 5 mL should be aspirated [29] ; for a tubing length of 213 cm (84 in.), 8 mL should be aspirated. [28] A second syringe, which has been heparinized, is then attached, and 3 mL of blood is aspirated and sent for blood gas analysis. If the blood is to be used for other tests, the second syringe does not need to be heparinized. The stopcock and line should be flushed after sampling to avoid clotting.

**Seldinger Technique for Arterial Cannulation**

An alternative method of placing an indwelling cannula is the Seldinger technique, [30] which is described in detail for

**Figure 19-10** Placement of an arterial line using the cutdown technique. Note that the catheter enters the surgical wound percutaneously to minimize bacterial entry into the healing wound and permit better stabilization of the catheter. Catheter entry of the vessel is more parallel to the vessel than is illustrated. Ligatures are used only to *temporarily* isolate the artery and to control bleeding. *The artery should not be tied off.* The catheter is secured by suturing the hub to the skin (see Fig. 19-9) .

venipuncture in Chapter 21 . A needle is percutaneously placed into the arterial lumen, as described previously. A guide wire is then placed through the needle into the vessel lumen, and the needle is removed. A catheter is then threaded over the wire, and the

wire is pulled out. As mentioned before, one commercial catheter permits the Seldinger technique to be performed without separate guide wire manipulation.

**Cutdown Technique for Arterial Cannulation**

The cutdown technique is another common method of obtaining arterial access. Cannulation is performed after direct visualization of the vessel. A cutdown can be performed on any artery but is most commonly reserved for the brachial and other distal limb arteries. After a site has been selected, the overlying skin should be surgically prepared with an iodophor solution. The physician then puts on sterile gloves and drapes the extremity. Local anesthetic solution is injected subcutaneously (SQ) in a horizontal line 2 to 3 cm long and perpendicular to the artery. Local anesthesia is not necessary if the patient is unconscious or is otherwise anesthetic at the cutdown site.

Using a scalpel with a No. 10 or 15 blade, the skin is incised along the anesthetic wheal. Underlying tissues are spread parallel to the artery with a mosquito hemostat. The pulse is palpated repeatedly throughout the procedure to ensure proper positioning. Once the surrounding soft tissue has been removed, exposing the artery for a distance of approximately 1 cm, the artery should be isolated by passing 2 silk sutures underneath it, using the hemostat. Strip away only enough perivascular tissue to expose the artery. Perivascular tissue will help to limit bleeding at the time of catheter removal. A catheter-over-the-needle device, such as that used in the percutaneous method, is then introduced through the skin just distal to the incision and advanced into the surgical site (Fig. 19-10) . [31] The arterial wall is punctured with the needle tip, and the catheter is threaded into the vessel lumen. When this has been accomplished, the 2 silk sutures, which have been used only to control the vessel, are removed, and the skin incision is closed. *The artery is not tied off as the vessel would be during a venous cutdown.* Firm pressure, as used following arterial puncture, should be applied over the cutdown site. The separation of the soft tissue during the procedure may allow considerable hemorrhage into the tissue if pressure is not applied. The catheter is secured to the skin in the same manner used for the percutaneous method (see Fig. 19-9) .

# ARTERIES

**Radial and Ulnar**

The radial artery is the artery that has most frequently been used for prolonged cannulation. A widespread collateral flow exists in the wrist. There are two major palmar anastomoses, known as *arches* (Fig. 19-11) (Figure Not Available) . The superficial palmar arch lies between the aponeurosis palmaris and the tendons of the flexor digitorum sublimis. The arch is formed mainly by the terminal ulnar artery and the superficial palmar branch of the radial artery. The other major communication of these 2 vessels, the deep palmar arch, is formed by connections of the terminal radial artery with the deep palmar branches of the ulnar artery. [32] Some collateral flow is almost always present at the wrist, with the deep arch alone being complete in 97% of 650 hand dissections. [33] Despite the findings of Coleman and Anson at autopsy, Friedman noted the absence of palpable ulnar pulses in 10 of 290 (3.4%) healthy children and young adults. [34] Interestingly, this was always a bilateral finding. Radial pulses were

present in 100% of the subjects.

A simple test has been recommended to determine the presence of collateral flow in the hand. This procedure has seen many modifications [35] [36] since being described by Allen in 1929. [37] In a cooperative patient, the basic Allen test is performed as follows: The examiner occludes the radial and ulnar arteries with digital pressure, and the patient is asked to tightly clench the fist repetitively to exsanguinate the hand. The hand is then opened, and the examiner releases the occlusion of the ulnar artery (Fig. 19-12) (Figure Not Available) . After several

**Figure 19-11** (Figure Not Available) Arterial anatomy of the hand and wrist. (From Ramanathan S, Chalon J, Turndorf H: Determining patency of palmar arches by retrograde radial pulsation. Anesthesiology 42:758, 1975. Reproduced by permission.)

**Figure 19-12** (Figure Not Available) Allen test. Before puncturing the radial artery it is important to be sure that a competent ulnar artery is present. This can be done as follows: *1,* The examiner compresses both arteries, and the patient repeatedly makes a tight fist to squeeze all the blood out of the hand. *2,* The patient then extends the fingers, and the examiner observes the blanched hand. *3,* Compression of the ulnar artery is released, and the examiner observes the hand fill with blood. If filling does not occur within 5 to 10 seconds, radial artery puncture should not be done. If brisk filling occurs, the test is then repeated with release of the radial artery to assess radial artery patency. If both radial and ulnar arteries demonstrate patency, the wrist may be used for arterial puncture. (From Schwartz GR [ed]: Principles and Practice of Emergency Medicine. Philadelphia, WB Saunders, 1978, p. 354. Reproduced by permission.)

minutes, the test is repeated with release of the radial artery. Rubor should rapidly return to the hand with release of either vessel.

An abnormal (positive) Allen test, suggestive of inadequate collateralization, is defined as the continued presence of pallor 5 to 15 seconds after release of the artery. [10] [32] [38] [39] If the return of color takes >5 to 10 seconds, radial artery puncture should not be performed. One must be careful to avoid overextension of the hand with wide separation of the digits, because this may compress the palmar arches between fascial planes and give a false-positive result. [38] Barber and associates [35] reported a modified Allen test that is useful in unconscious or anesthetized patients who cannot clench their fists. An Esmarch bandage is used to exsanguinate the hand, and the test is performed as previously described. Time permitting, performance of some variation of the Allen test is desirable before ulnar or radial puncture for cannulation or blood gas sampling.

A study by McGregor has shown that positive Allen test results may be false positives when further evaluated by intra-arterial fluorescein angiography. [40] Slogoff and colleagues, in a study of 1700 radial artery cannulations for monitoring purposes, reported 16 cases of radial artery cannulation in patients with abnormal Allen tests, none of whom developed ischemia or abnormality of radial flow after cannulation. [41] Of note, the Allen test was performed on only 411 of their 1700 patients, giving an abnormal result 4% of the time. Cardiovascular surgical patients of the Texas Heart Institute have been monitored with radial artery cannulation for 20 years without routine performance of the Allen test. Nonetheless, when alternative sites exist, the results of an Allen test should be documented on the chart for medicolegal reasons, and an alternative site used. A normal Allen test is desirable, but it is not a guarantee against

digital ischemia following radial artery cannulation. [42]

Once adequate collateral flow has been ascertained, arterial puncture may be performed. At the wrist, the radial artery rests on the flexor digitorum superficialis, flexor pollicus longus, and pronator quadratus, and against the radius. [33] Just distal to the styloid process of the radius, the artery winds around the lateral aspect of the wrist to the dorsum of the hand. The pulsation of the artery should be isolated on the palmar surface of the wrist, where it is superficial. Dorsiflexing the wrist at about a 60° angle over a towel or sandbag, with or without fixing the wrist to an arm board, will help isolate and fix the artery (see Fig. 19-7) (Figure Not Available) . [10] [43] [44]

The ulnar artery may occasionally be used but is technically more difficult to puncture than the radial artery because of its smaller size. At the wrist, the ulnar artery runs along the palmar margin of the flexor carpi ulnaris in the space between it and the flexor digitorum sublimis. [33] In this area it is in intimate contact with the ulnar nerve. The ulnar nerve and artery pass into the hand just radial to the pisiform bone. The ulnar artery can often be made more accessible with dorsiflexion of the wrist.

**Brachial**

Barnes and colleagues [8] monitored 54 patients with an 18- or 20-ga Teflon catheter percutaneously placed in the left brachial artery at the antecubital fossa. None of these patients developed Doppler evidence of brachial artery obstruction; however, partial to complete obstruction of the radial artery was noted in 2 patients, and of the ulnar artery in 1 patient. None of these 3 patients exhibited ischemic symptoms. These researchers also noted no clinical evidence of ischemia in 1000 brachial catheterizations over a period of 3 years. Thus the brachial artery appears to be a safe site for arterial puncture, although collateral circulation in this area is not as great as in the hand.

The brachial artery begins as the continuation of the axillary artery and ends at the head of the radius, where it splits into the ulnar and radial arteries. The preferred site of puncture of the brachial artery is in or just proximal to the antecubital fossa. In this region the vessel lies on top of the brachialis muscle and enters the fossa underneath the bicipital aponeurosis (Fig. 19-13) (Figure Not Available) . The median nerve runs along the medial side of the artery. Owing to reduced collateral circulation and the necessity of maintaining the arm in extension

**Figure 19-13** (Figure Not Available) The right brachial artery and its branches. (From Christensen JB, Telford IR: Synopsis of Gross Anatomy. New York, Harper & Row, 1966. Reproduced by permission.)

for puncture or prolonged cannulation, more distal vessels are preferred when the upper extremity is chosen for cannulation.

**Axillary**

Axillary artery cannulation as described by Adler and coworkers [45] is also a safe means of monitoring arterial blood pressure for a long period of time. The left axillary artery is

preferred in order to decrease the possibility of cerebral embolization of flush solution or thrombus. The path from the left subclavian to the left carotid artery is less direct than on the right side, whereas the vertebral arteries are equally vulnerable.

To cannulate the axillary artery, the arm is held in 90° abduction. The axillary pulse is then palpated high in the axilla between the insertion of the pectoralis major and the deltoid muscles. The artery may then be cannulated percutaneously with or without a Seldinger guide wire. This site is technically more difficult and time consuming and probably should be avoided in the emergency department. No studies have been reported regarding large numbers of axillary punctures; therefore, the relative safety of this location cannot be determined.

## Dorsalis Pedis

The dorsalis pedis artery is a continuation of the anterior tibial artery. Anterior to the ankle joint, the dorsalis pedis runs from approximately midway between the malleoli to the posterior end of the first metatarsal space, where it forms the dorsal metatarsal and deep plantar arteries. The lateral plantar artery, which is a branch of the posterior tibial, passes obliquely across the foot to the base of the fifth metatarsal. The plantar arch is completed where the lateral plantar artery joins the deep plantar artery between the first and second metatarsals. On the dorsum of the foot, the dorsalis pedis artery lies in the SQ tissue parallel to the extensor hallucis longus tendon, between it and the extensor digitorum longus (Fig. 19-14) (Figure Not Available) . [5] The artery should be cannulated in the midfoot region. Although this vessel is amenable to cutdown, the vascular anatomy of the foot is quite variable. This is of no consequence if a pulse can be palpated, but Huber, in his dissection of 200 feet, noted the dorsalis pedis artery to be absent in 12%. [46] In 16% of patients, the dorsalis pedis artery provides the main blood supply to the toes. [47] Collateral flow can be determined with a modified Allen test using the posterior tibial and dorsalis pedis arteries, but this is not as easily performed in the foot as in the hand. The pressure wave obtained with an electronic transducer attached to the dorsalis pedis artery will be 5 to 20 mm Hg higher than that of the radial artery and, in addition, will be delayed by about one tenth of a second. [48]

## Femoral

Currently, the femoral artery is the second most commonly used vessel for prolonged arterial cannulation. Several studies have demonstrated the efficacy and safety of using this vessel, and indeed, several investigators suggest that it should be the vessel of choice. [49] [50] [51] [52] The femoral artery is the direct continuation of the iliac artery. The femoral artery enters the thigh after passing behind the inguinal ligament, where, in most patients, it may be easily palpated at a point midway between the pubic symphysis and the anterior superior iliac spine. When puncturing this vessel, care must be taken to avoid the femoral nerve and vein, which are in close proximity to the artery on the lateral and medial sides, respectively (Fig. 19-15) (Figure Not Available) .

A longer cannula is required for the femoral artery owing

**Figure 19-14** (Figure Not Available) A 20-ga catheter in the dorsalis pedis artery, illustrating the

relationship to surrounding tendons. The catheter is secured with Steri-Drape. Splinting is not needed. (From Johnstone RE, Greenhow DE: Catheterization of the dorsalis pedis artery. Anesthesiology 39:655, 1973. Reproduced by permission.)

**Figure 19-15** (Figure Not Available) The right femoral vessels and some of their branches. The femoral nerve (not shown) lies lateral to the artery and may be deep to the artery. (From Warwick R, Williams PL [eds]: Gray's Anatomy. 35th ed. Edinburgh, Churchill Livingstone, 1973, p 676. Reproduced by permission.)

to the relatively greater depth at which it lies. The Seldinger technique is especially useful for this site, enabling placement of a 15- to 20-cm plastic catheter for prolonged monitoring. Catheter-over-the-needle devices may also be used but should be at least 10 cm long. Use of catheter-through-the-needle devices has been reported [51] but should be avoided because of the possibility of leakage around the catheter, which may occur with high arterial pressures owing to the loose fit of the cannula in the hole in the vessel wall. Regardless of the device used, the needle should enter the skin at an angle of about 45° instead of the usual 15° to 20°.

The extremely large ratio of arterial diameter to catheter diameter is thought to beneficially reduce the incidence of thrombosis, particularly total occlusion. However, occlusions have been reported with femoral cannulation for monitoring purposes. [53]

A commonly postulated disadvantage of this site is the possibility of increased bacterial contamination because of its proximity to the warm, moist groin and perineum; however, no studies confirm this hypothesis. [54] The femoral area is inconvenient for the patient who is awake and mobile, especially if the patient is capable of sitting in a chair. In spite of these theoretic difficulties, some large hospitals use femoral arterial lines almost exclusively, and the intensive care nursing staff is often more comfortable caring for these lines than those at other sites.

### Umbilical and Temporal

In the neonate, arterial access can be accomplished through the umbilical artery for a short period of time. After this artery closes, the temporal artery provides a safe alternative. Prian described the use of the temporal artery, noting its accessibility and the lack of clinical sequelae if it undergoes

thrombosis. [55] The cutdown method should be used with a 22-ga catheter after the artery's course has been traced with an ultrasonic flow detector. Because of the increasing accuracy of ear oximeters and the use of capillary blood gases for pH determination, prolonged arterial cannulation will become less frequent during infant care. Further discussion of infant arterial cannulation is provided in Chapter 18 .

## COMPLICATIONS

Long-term arterial cannulation is safe if care is taken to avoid complications. Almost all the difficulties one may encounter can be avoided or their incidence markedly decreased if one adheres to a few simple principles. Reported clinical sequelae of

arterial puncture and cannulation range from simple hematomas to life-threatening infections and exsanguination. The incidence of complications varies with the site and method of cannulation and with the skill and concern of the patient's physicians and nurses. It is difficult to compare complication rates at various sites, because most published studies have primarily used the radial artery. Many studies also report complications of puncture for arteriography and other procedures unrelated to long-term cannulation.

A commonly encountered problem is hematoma formation at the puncture site. Zorab [15] reported this complication in 50% of catheterizations. The bruising was of minimal clinical significance in Zorab's study, but leakage, when it occurs around the catheter or from the puncture site after the catheter's removal, can be of danger to the patient. Compression neuropathy secondary to bleeding has been reported after brachial artery puncture in anticoagulated patients; in some cases, surgical decompression has been necessary. [4] The large amount of soft tissue surrounding the femoral artery makes bleeding in this area difficult to control. [56] Large hematomas are not uncommon after femoral artery catheterization; indeed, Soderstrom and associates [49] reported 2 cases of bleeding that required transfusion after femoral puncture. Another patient suffered a large hematoma that became infected and required incision and drainage.

Prevention of bleeding complications may be accomplished with frequent careful inspection of the puncture site and with the use of prolonged compression after removal of the catheter or needle. Firm pressure should be maintained for at least 10 minutes after removal of a peripheral artery catheter and for a longer period of time after femoral cannulation or if the patient is anticoagulated. Five minutes of pressure is sufficient after puncture for a blood gas sample in an individual with normal coagulation. Exsanguination, a related complication, may occur if the arterial line apparatus becomes disconnected. This is more common in the obtunded or combative patient, and restraints are often required for patients with indwelling arterial cannulas. Exsanguination should not occur if tight connections are maintained throughout the system and if frequent, careful inspections of both the circuit and the patient are made.

Serious infections rarely complicate arterial cannulation. However, the incidence of catheter-related infections increases with prolonged cannulation. [54] [57] Catheters placed with sterile technique have an extremely low rate of infection up to 96 hours. Catheters changed over a guide wire every 96 hours have an infection rate of about 10% at the radial and femoral sites. [54]

Most infections begin as local infections at the puncture site and remain localized, although systemic sepsis has been reported. [56] Radial and femoral sites have a similar incidence of complications, but axillary cannulations seem to have a much higher incidence of infection, although no large studies of cannulation at this site exist. [54] [57] Arterial cannulas are more prone to infectious complications than other vascular catheters. Many mechanisms have been proposed for this. [58] [59] [60] The arterial pressure monitoring system usually consists of a long column of fairly stagnant fluid and is subject to frequent manipulation. Stamm and colleagues [59] found that patients were at greater risk for systemic infection if they had an arterial line and required frequent blood gas determinations than if they had the cannula alone. The sampling stopcock is

a site of frequent bacterial contamination.

The risk of infection also increases as the duration of cannulation is prolonged. Catheters should be changed after 4 days if continued monitoring is necessary. [57] [61] In addition, Makai and Hassemer [60] recommend changing the entire fluid-filled system, including transducer chamber-domes and continuous flow devices, every 48 hours. Shinozaki and coworkers [62] demonstrated a marked reduction in equipment contamination when the continuous flush device was located just distal to the transducer, as opposed to the device being positioned closer to the three-way stopcock used for sampling. This setup reduces the length of the static column of fluid between the sampling stopcock and the transducer. As mentioned previously, a drop of iodophor or antibiotic ointment applied to the puncture site decreases the incidence of local wound infection. [61]

Thrombosis of the vessel in which the cannula is placed is another frequently encountered problem. The incidence with which this occurs varies with the method used to determine the presence of the clot. Bedford and Wollman [7] found a >40% occlusion rate when radial artery catheters were left in place for >20 hours. All of these occluded vessels eventually recanalized. Angiographic studies show deposition of fibrin on 100% of the catheters left in place for >1 day, although clinical evidence of ischemia secondary to occlusion with thrombus is present in <1% in most studies. [6] Most reports of nonangiographic catheterizations that mention thrombosis are reports of studies of the radial artery. Therefore, it is difficult to compare the incidence of thrombosis at other sites, although during the 176 femoral catheterizations of Soderstrom and coworkers and Ersoz and associates, [49] [51] dorsalis pedis pulses were decreased in only 2 patients, and no clinical signs of ischemia were noted. Larger catheter sizes, trauma during cannulation, and the presence of atherosclerosis have all been postulated to increase the incidence of thrombosis; however, conflicting studies abound. Downs and colleagues associated tapered catheters with an increased incidence of thrombosis. [11]

Arterial spasm after puncture can predispose to thrombus formation and can even lead to ischemic changes without fibrin deposition. Successful reversal of spasm after intra-arterial lidocaine, reserpine, and phentolamine has been reported, but no reliable studies of efficacy in this situation have been published. [63] Thrombosis can be minimized by decreasing the duration of catheterization, by proper flushing, and by using larger arteries. Surgical embolectomy or thrombectomy is rarely required, because the smaller vessels that are most likely to occlude usually have good collateral

circulation. A normal (negative) result on an Allen test or a similar test suggests but does not ensure adequate collateral flow. [42] The larger femoral artery, which has poor collateralization, rarely occludes with catheterization for monitoring purposes.

Another complication of thrombosis is occlusion of the catheter. Times until occlusion of radial and femoral artery catheters have been compared, and it was noted that radial cannulas became occluded at an average of 3.8 days, whereas femoral cannulas occluded after 7.3 days. [49] The importance of this comparison is minimal if the clinician follows infection prophylaxis guidelines and changes arterial catheters after 4 days.

A few less common complications are easily prevented. One such complication, which occurs only with the percutaneous catheter-through-the-needle method, is catheter embolization. Once the catheter has been placed through the needle, it should never be pulled back, because the end of the catheter may be sheared off by the sharp needle bevel. If this occurs, surgical removal of the catheter tip is necessary.

Skin necrosis is a complication of radial artery cannulation involving an area of the volar forearm proximal to the cannula. [64] [65] Wyatt and colleagues [64] believe this is secondary to the poor blood supply of this area and state that taking the precautionary steps described previously prevents or decreases the incidence of necrosis. One feared complication of indwelling radial and brachial arterial catheters is the occurrence of a cerebrovascular accident secondary to embolization from flushing of the catheters. [11] [66] As little as 3 to 12 mL of flush solution have been shown to reflux to the junction of subclavian and vertebral arteries. [66] A fatality due to air embolism from a radial artery catheter has been reported and was re-created in a macaque model. [67] Although these animals are much smaller (7 kg) than an adult human, as little as 2.5 mL of air introduced at a relatively low flush rate was found to embolize in a retrograde fashion to the brain. Cerebral embolization can be prevented with the use of continuous flush systems (3 mL/hour) and by ensuring the integrity of the tubing and transducer systems to prevent air entry. In addition, small volumes (<2 mL) of intermittent flush solution should be used.

Complication rates also vary according to the method of arterial cannulation. Mortensen [68] studied the 3 main techniques (discussed in Techniques), but unfortunately, most of his arterial cannulations were for angiographic purposes. The complications associated with prolonged cannulation time are therefore underrepresented. For Mortensen's series, cutdown arteriotomy exhibited the lowest incidence of complications (7.7%), whereas the Seldinger technique had a complications incidence of 17.7%. Complications of percutaneous cannulation were 11.3%. Apparently, false passage of the guide wire, the catheter, or both were associated with increased intimal damage and complications. *It is imperative that the wire or catheter be advanced only if no resistance is met!*

In actuality, arterial puncture and cannulation are safe procedures when care is taken and basic principles are kept in mind. The operator should be skilled and should seek an atraumatic insertion. Once the monitoring system has been set up, it should be manipulated as little as possible. Any handling should be performed with a flawless aseptic technique. The tubing and other fluid-filled devices should be changed every 48 hours, and catheters should be inserted into a vessel that provides a vessel-to-catheter ratio that is as great as possible without compromising other needs. If these principles are followed and the patient and system are carefully inspected at frequent intervals, complications of arterial puncture and cannulation can be minimized.

## INTERPRETATION

An indwelling arterial cannula can provide valuable information about the hemodynamic status of a patient (through continuous pressure monitoring) and about the patient's

respiratory and metabolic status (through intermittent sampling for blood gas analysis and other blood tests). The partial pressure of carbon dioxide and pH of the blood can be used to define 4 major groups of metabolic derangement: respiratory acidosis or alkalosis, and metabolic acidosis or alkalosis. Rarely will a disorder be strictly classified into 1 of these groups; however, a simple chart such as that shown in Figure 19-16 (Figure Not Available) will assist one in determining the relative effects of metabolic and respiratory influence on the blood pH. See also the discussion in the Appendix. A rough estimate of the contribution of respiratory factors may be made by assuming that for every 10 torr (mm Hg) that the $P_{CO_2}$ varies from 40, the pH will inversely vary 0.08 pH unit from 7.4. Adequacy of oxygenation of the blood can be determined from the measured $P_{O_2}$ of the arterial blood and from the known concentration of oxygen that the patient is inspiring. To avoid iatrogenic complications of intensive care, one must be absolutely certain that the data are from an arterial sample that has been properly analyzed before basing

**Figure 19-16** (Figure Not Available) In vivo nomogram showing bands for uncomplicated respiratory or metabolic acid-base disturbances. Each "confidence" band represents the mean ± 2 SD for the compensatory response of normal subjects or patients to a given primary disorder. Ac, acute; Chr, chronic; Resp, respiratory; Met, metabolic; Alk, alkalosis; Acid, acidosis. (From Thorn GW, Adams RD, Braunwald E, et al [eds]: Harrison's Principles of Internal Medicine. 8th ed. New York, McGraw-Hill, Inc, 1977, p 377. Reproduced by permission.) (See Appendix for more detail.)

one's treatment decisions on the numbers obtained. Not uncommonly, one may accidentally puncture a vein when attempting to obtain an arterial blood sample. Furthermore, false readings may result if the sample is not free of air bubbles, not promptly chilled, and not analyzed within 20 to 30 minutes. Although still controversial, blood gas values that are *uncorrected* for body temperature appear more appropriate for guiding therapy in hypothermic patients. [69] [70]

An indwelling arterial catheter also provides continuous blood pressure monitoring. The trend of a patient's pressure helps one assess the effect of various therapeutic interventions. The absolute systolic and diastolic pressures measured will vary at different catheter sites, with higher peak systolic pressures measured at the periphery; the pressures will also be higher when measured in the distal lower limb. [12] [48] A wide variance between direct arterial pressure and pressure measured with a standard pneumatic cuff will always exist in some patients. Data averaged over a population group, however, compare fairly well. [12] For this reason, the cuff pressure and that displayed on the monitor should be compared regularly. A change in their relationship may be the first indication of difficulties with the direct measuring system. Auscultatory methods usually give a slightly lower value than direct measuring systems.

Waveform analysis may also provide an early indication of thrombosis in the arterial catheter. Many variables affect the waveform, including cardiac valvular disease, arteriosclerosis, and other peculiarities of an individual's cardiovascular system that may contribute to pulse wave reflections. [71] Waveforms may vary tremendously among patients, but after an adequate monitoring system has been established, a change in an individual's pressure wave is usually indicative of thrombosis or other malfunction in the monitoring system. A change in waveform may also indicate a change in the patient's cardiovascular status, such as a papillary muscle rupture. Once again, before making a

therapeutic decision based on an electronically generated number, the patient should be rechecked with a pneumatic cuff; this device is less fallible than the electromechanical system.

## CONCLUSION

As intensive care knowledge and technology grow and develop, cannulation of the arterial system may become a more routine procedure. Nonetheless, devices have been developed that in some cases may decrease the frequency with which this procedure is performed. Oximeters can determine the quality of oxygenation of the blood percutaneously and are becoming more accurate and sophisticated (see Chapter 6) . Electronic sphygmomanometers are being refined for continuous indirect blood pressure monitoring. However, these devices will not soon replace the indwelling arterial cannula, because of the need for frequent blood sampling for chemical and hematologic analysis.

Arterial puncture and cannulation are invaluable aids to the emergency and critical care physician. Long-term catheterization is a safe procedure when the catheter is placed, maintained, and removed with care. The radial artery is the most favored location for puncture, but as more experience is gained and reported with femoral artery catheterization, the latter may become a more frequently used site. Selection of either site is associated with a low complication rate and should be determined by the skill of the physician and the nursing team and the relative convenience and comfort of the patient.

# Chapter 20 - Peripheral Intravenous Access

**Edith L. Hambrick, Georges C. Benjamin**

Peripheral IV catheterization is one of the mainstays of modern medicine. It is a common procedure done by all levels of health care professionals, including physicians, nurses, physicians' assistants, nurse practitioners, and emergency medical technicians. The procedure allows access to the peripheral circulation for blood sampling, fluid and nutrition administration, and administration of medications. Generally peripheral IV catheterization can be accomplished in adults and children in less than 5 minutes if the patient has adequate peripheral circulation and normal veins. [1] [2] [3]

Although bloodletting has been described since the time of Hippocrates around 460 B.C., [4] one of the first documented descriptions of IV therapy, in the form of a blood transfusion, was made by an Italian physician, Giovanni Francisco Colle, in 1628. [5] In 1654, Francesco Folli was said to have used a combination of a silver tube, bone cannula, and animal blood vessel to accomplish a blood transfusion. [4] In 1662, Johann Daniel Major, a German physician, is credited with being the first to inject a medicinal substance into the vein of a human successfully. [6]

Initially steel needles were used for catheterization; however, in the early 1950s, plastic catheters were introduced for continuous IV infusions and over time have largely replaced those made of steel.

## INDICATIONS AND CONTRAINDICATIONS

Peripheral IV cannulation is performed to provide access to the patient's circulatory system. This access can be used for

phlebotomy, delivery of medication and fluids, and short-term nutrition administration. Peripheral lines are also placed in patients who have potentially life-threatening conditions as a means of ensuring adequate venous access should a problem develop. [9]

Establishment of IV access is essential during cardiac arrest and major trauma. The role of high-volume resuscitation before hemorrhage is controlled and definitive care is available remains controversial (see Chapter 23) . [10] In patients with normal perfusion, delivery times to the central circulation with peripheral venous access are similar to those attained with central venous access. [11] During closed-chest cardiopulmonary resuscitation (CPR), medication is delivered to the left ventricle more than a minute faster with central venous lines than with peripheral venous access. The former is the preferred route, when available. [12]

Short-term nutrition and hyperalimentation, primarily intralipids, can be administered peripherally. However, all other hyperalimentation must be given through a central IV

line because of the high tonicity of the solution.

The use of a *saline lock* catheter system (formerly termed *heparin lock* because of its use with a heparin solution) is preferable when access to the circulation is needed for medication delivery and limited IV fluid administration is anticipated. This is especially useful in cases of cardiac, renal, or hepatic failure. It has been recommended by one group for use in the out-of-hospital setting in lieu of the traditional continuous IV infusion when prophylactic access or access only for administration of bolus medications is desired. [13]

Because of the potential for fluid extravasation or inadequate volume flow, peripheral IV lines should not be started in an extremity in which massive edema, burns, traumatic injury, sclerosis, phlebitis, or thrombosis are present. In addition, the ipsilateral arm of a patient who has undergone a mastectomy or who has neck trauma or an indwelling fistula also should be avoided, if possible. In patients with chest, abdominal, or proximal extremity trauma, the vein selected for an IV line should not empty into the affected area, because the integrity of the proximal veins cannot be ensured. For example, it is preferable for patients with gunshot wounds to the abdomen to have IV lines started in their upper extremities, neck, or chest, rather than in the lower extremities.

The potential risk of inoculating the central circulation with bacteria is increased when an IV line is started in an area in which cellulitis is present, and therefore local cutaneous infection is a contraindication. Patients who have renal shunts or fistulas should have IV lines placed in the opposite extremity because of an increased risk for infection or thrombosis of the shunt or fistula. The extremity with a shunt or fistula can be used by an experienced practitioner in an emergency situation if extreme aseptic precautions are used and arterial delivery of the solution is not contraindicated.

## ANATOMY

In the upper extremity, on the dorsal surface of the hand, the veins collect blood from the dorsal and oblique communicating veins of the fingers, which form the dorsal plexus (see Fig. 22-2) . These in turn drain into the superficial radial and ulnar veins on the lateral and medial sides of the forearm, respectively. The cephalic vein is located on the radial border of the forearm and receives branches from the small veins in the forearm. The cephalic vein ascends the arm, gives off the median cephalic vein, and empties into the axillary vein.

The basilic vein collects blood from the veins of the ulnar portion of the posterior forearm. It then joins the median cubital vein and ascends on the medial portion of the arm. The axillary vein begins at the lower border of the teres major muscle as a continuation of the basilic vein and ends at the outer border of the first rib, where it becomes the subclavian vein. The subclavian vein unites with the internal jugular to form the brachiocephalic (innominate) vein. The right and left brachiocephalic veins join to form the superior vena cava, which empties into the right atrium of the heart.

In the lower extremity, on the dorsal surface of the foot, the dorsal digital veins receive blood from the plantar veins and then join with the dorsal metatarsal veins to form the

dorsal venous arch. On the sole of the foot, superficial veins form the plantar cutaneous arch, which drains into the medial and lateral marginal veins. The medial marginal vein drains into the great (long) saphenous vein at the ankle, which, as it ascends, collects tributaries from superficial and deep veins and ends at the femoral vein in the proximal thigh (see Fig. 22-1) . The plantar digital veins drain into the plantar metatarsal veins, forming the deep plantar venous arch.

The arch then drains into the medial and lateral plantar veins, which receive tributaries from the great and small saphenous veins to form the posterior tibial vein. The posterior and anterior tibial veins unite and form the popliteal vein. The femoral vein is a continuation of the popliteal vein. After passing behind the inguinal ligament, the femoral vein becomes the external iliac vein. The internal iliac, which arises from a confluence of veins draining the pelvis, joins with the external iliac to form the common iliac. The inferior vena cava is formed by the union of the common iliac veins and in turn empties into the right atrium of the heart.

The reader is referred to Chapters 22 through 24 for additional discussion on anatomy.

## EQUIPMENT

The necessary items for achieving IV access are shown in Table 20-1 . Povidone-iodine, 70% alcohol, or both should be used to clean the skin. A tourniquet is necessary to occlude the venous blood flow. A flexible rubber tube, a

| **TABLE 20-1** -- Materials Required for Peripheral IV Line Insertion |

| ¼-inch tape |
| Latex gloves |

commercial rubber tourniquet with Velcro, or a sphygmomanometer inflated to 10 to 15 mm Hg below the systolic blood pressure serves this purpose. Sterile gauze pads are used to wipe away excess povidone-iodine or alcohol and to stop any bleeding from the phlebotomy site after withdrawal of a catheter. An arm board may be necessary if the line is placed over a joint or requires stabilization. Additional items such as tape, topical antibiotics, and appropriate dressings are also required.

Several catheter types are commonly used to gain peripheral venous access: a hollow steel needle, a plastic catheter over a hollow steel needle, a plastic catheter inserted through a hollow steel needle, or a plastic catheter over a flexible metal guide wire. [9] The catheter over the needle is the most common type currently used for peripheral access. Multilumen catheters (e.g, Twin-Cath, Arrow International, Reading, Pa) are useful when multiple medicines must be administered simultaneously.

## PREPARATION

To allay patient fears, reduce apprehension, and correct misinformation, the purpose, methods, and outcome of the procedure should be explained clearly at the onset by the practitioner when the patient is conscious and time permits. Before initiating IV lines, all of the items necessary for performing the procedure should be assembled and placed in convenient proximity to the practitioner. This is especially important if the practitioner is performing the procedure alone. As with all invasive procedures, universal blood

precautions should be taken, which includes wearing latex gloves, at a minimum. [14] If the propensity for blood splatter is high (e.g., in an uncooperative or delirious patient), a gown, face mask with eyeshield, and other protective equipment should be donned as needed (see Chapter 75) .

## Site Selection

Straight, large, bifurcated, easily accessible peripheral veins with healthy subcutaneous (SQ) tissue are ideal for cannulation (Fig. 20-1 *A*). The veins of the upper extremity are generally chosen to initiate IV lines because many potential sites are available and because the patient will be more comfortable. The most distal vein should be selected first if several sites are available. This strategy allows the practitioner to use a more proximal site in the event that the initial attempt is unsuccessful and avoids proximal fluid leakage from a previous puncture wound during fluid infusion. The veins of the hand and the volar aspect of the forearm are the preferred sites. The veins of the antecubital space or other upper extremity joints, although popular, are best avoided as a primary site because of vein tortuousity and the need to immobilize the patient's arm to prevent kinking of the catheter. The foot and lower leg are acceptable secondary sites. The external jugular vein also may serve as a site for venous access, particularly in infants and adults without suitable arm veins. This site may negate the need for central venous catheterization in IV drug users (Fig. 20-1 *B*). A percutaneous approach to the brachial vein has been described and is useful in patients who lack other peripheral sites. [15] Evidence in dogs suggests that 90% of peripheral IV fluid reaches the central circulation, even when

**Figure 20-1** *A,* Prominent veins on the dorsum of the hand. *B,* The external jugular vein may be cannulated in the same manner as any other peripheral vein, which often negates the need for central venous catheterization. This site is especially useful in obese adults, infants, and IV drug users. The major disadvantages are that flow is very dependent on the position of the neck (a significant problem in children and obtunded or restless adults), and valves may abut against the tip of the catheter. Air embolism from a disconnected catheter is another potential hazard with this access route.

it is injected under an inflated pneumatic antishock garment (PASG). [16] However, the injected fluid must be infused under a pressure greater than that in the PASG.

## Intravenous Line Assembly

IV fluid, an IV tubing set, and a primary administration set are selected appropriately for the clinical situation. A standard nonshock resuscitation set is shown in Figure 20-2 . If medication is being administered IV, a shorter secondary administration set is also needed (Fig. 20-3) . The cap and protective tabs should be removed from the container and drip chamber end of the IV tubing. After closing the regulating clamp, the spiked end of the tubing is then inserted fully into the receptacle on the solution container (Fig. 20-4) . The container is then turned over so that the tubing is dangling from below. The drip chamber should be pinched so that it fills halfway (Fig. 20-5) . The regulating clamp is

**Figure 20-2** Standard nonshock resuscitation set.

**Figure 20-3** Secondary administration set to "piggyback" medication into the main IV infusion.

**Figure 20-4** Insertion of the spiked end of tubing into an IV fluid bottle.

**Figure 20-5** Pinching of the drip chamber to fill the bulb halfway before starting the continuous infusion.

then opened, and fluid is allowed to fill the tubing completely, expelling all air bubbles. The bottle is then hung from an IV pole higher than the level of the insertion site.

## Placement of the Tourniquet

The tourniquet is placed 3 to 4 cm proximal to the site of the phlebotomy, taking care not to pinch the patient's skin (Fig. 20-6 *A*). It is applied so that arterial blood continues to flow into the extremity, but venous flow is occluded. Often the practitioner must start the IV line without assistance. Therefore, the flexible rubber tube should be tied so that it can be released with one hand as the practitioner steadies the catheter with the other (Fig. 20-6 *D*). The rubber tube is stretched and, with tension maintained (Fig. 20-6 *A*), crossed in front of the extremity, making an "X," and leaving one portion longer than the other (Fig. 20-6 *B*). [17] The middle of the longer end is tucked under the stretched tube, creating a loop and leaving the tip dangling free (Fig. 20-6 *C* and 20-6 *D*).

After application of the tourniquet, the veins may not become prominent, or the practitioner may not adequately feel the distended veins subcutaneously. Several explanations are possible. The tourniquet may be too tight, occluding both venous and arterial blood flow; the patient may have inadequate blood volume; or the veins may be sclerosed. To determine whether the tourniquet is too tight, the practitioner should feel the pulses distal to the tourniquet. If the pulse is absent, the tourniquet should be released and reapplied so that only the venous flow is occluded. If a sphygmomanometer is used, the cuff is inflated to 10 to 15 mm Hg less than the systolic pressure. A blood pressure cuff tourniquet has been shown to produce greater venous distention than an elastic tube tourniquet. [18]

The patient's veins should be checked again for sclerosis or thrombosis. If venous pathology is the cause of inadequate venous prominence, another site should be selected. If inadequate volume or shock is suspected as the cause of peripheral venous collapse, central venous lines, peripheral venous cutdown, or intraosseous infusion can be used until peripheral veins become more prominent.

## Adjuncts for Venous Dilation

The practitioner may still have difficulty locating a vein, even though the patient has a normal blood pressure, there is no previous exposure to irritating medications, and the tourniquet is applied properly. Other techniques for vein location can be used. A warm, moist towel can be applied to the site for several minutes, or an infrared light can be allowed to radiate over the site (not in contact with the skin) to cause vasodilation of the veins. [17] If this method is chosen, patients

**Figure 20-6** Application of a tourniquet. *A,* Placement of a tourniquet 3 to 4 cm proximal to the planned insertion site. *B,* Crossing of the ends of the tourniquet under tension. *C,* Tucking the longer end under the "X" to make a loop. *D,* One-handed technique for releasing the tourniquet.

should have normal skin and normal sensation to avoid burns. Tapping sharply over the vein can result in mechanical reflex dilation of the vascular walls, [17] but the tapping must be light enough to avoid reflex vasoconstriction from pain. Active or passive pumping of the extremity can also distend the veins by enhancing flow. Although rarely used, reactive hyperemia can be created by completely occluding the circulation with a sphygmomanometer for a few minutes and then releasing the sphygmomanometer to 10 to 15 mm Hg below the diastolic pressure. [17] This technique should not be used in patients at risk for peripheral vascular disease or coagulopathies.

Nitroglycerin ointment (0.4%) applied to the venipuncture site has been shown to facilitate venous dilation in children younger than 1 year of age. [19] In adults, a 2% nitroglycerin ointment increases the success rate of cannulation of small-caliber veins without significant side effects. [20] This is accomplished by placing ¼ inch of the ointment over the planned puncture site, spreading it over a 2.5 cm2 area for 2 minutes, and then removing the ointment before skin preparation.

A venous distention device has been used to augment venous filling in the nonemergency patient. [18] By using this device, peripheral venous cannulation can be achieved in 90% of patients who have difficult-to-access veins. [21] Complications with its use are minimal and include mild discomfort and petechiae. This device is still experimental and is not available for common use, and therefore, its role in the care of critical patients remains undefined.

**Site Preparation**

The skin should be cleaned with a povidone-iodine solution; a circular motion should be used, starting at the planned site of insertion and spiraling outward for 4 to 5 cm. After allowing this area to dry, 70% isopropyl alcohol is applied by using the same motion. Patients with iodine sensitivity can be cleaned with 70% alcohol alone if necessary, but this method may be less effective than that using povidone-iodine. [22]

Most catheters can be placed without anesthesia. When many punctures are

anticipated, large-bore catheters are placed, or patient anxiety is a factor, 0.5% or 1% lidocaine (Xylocaine), 0.1 mL placed intradermally using a 27-ga needle and 1-mL syringe, can be used at the puncture site to provide local anesthesia for approximately 20 minutes. [23] A more temporary anesthetic effect (3 minutes) can also be obtained by intradermal injection of 0.1 mL of sterile normal saline. [23] A solution of 0.9% benzyl alcohol and normal saline has been shown in one study to be superior to normal saline alone for this purpose. [24] In general, topical anesthetics are of little value because of poor penetration through the skin. However, eutectic mixture of local anesthetics (EMLA), a topical mixture of lidocaine and prilocaine base, may be an exception to this generalization; in children, the mixture seems to be well tolerated and effective. [25] Disadvantages to its use include the long application time (1 hour), the need for an occlusive dressing, and occasional local irritation, probably from the adhesive tape.

## CATHETER INSERTION

The skin should be grasped and *pulled taut to stabilize the vein* with the nondominant hand (Fig. 20-7 *A*). The IV catheter is held in the dominant hand, and the skin is rapidly punctured by a sterile catheter, bevel up, at a 30° angle and parallel to the vein. After entering the SQ space, the needle should be aligned in a parallel fashion with the surface of the extremity and along the long axis of the vein (Fig. 20-7 *B*). This will lessen the chances of perforating the back wall of the vein. A technique favored by many practitioners is to enter at the junction of two veins as a means of ensuring cannulation. Once into the skin, the catheter is advanced until a "pop" is felt and blood is seen in the flash chamber of the catheter or in the syringe (Fig. 20-7 *C*). The catheter is then advanced over the needle to the hub and the needle is removed (Fig. 20-7 *D*), with pressure placed on the proximal vein over the catheter tip. A syringe can then be connected to the catheter hub for phlebotomy before infusion (Fig. 20-7 *E*). The IV tubing is then attached to the hub of the needle or catheter (Fig. 20-7 *F*); the tourniquet is released; and after opening the regulating clamp, fluids are infused at the preselected rate.

Occasionally the catheter system will not advance because of small vessel diameter or a spasm of the vessel wall. The practitioner can remove the needle and connect the IV tubing. As the infusion is slowly started, the catheter can often be advanced slowly. This technique may be especially valuable in infants or in adults with limited available veins. This procedure is used only when partial cannulation is ensured and the solution is nonirritating.

If a heparin or saline lock is desired (Fig. 20-8) , the hub of the catheter is sealed with a catheter lock, and 1 mL (10 or 100 units/mL) of heparin sodium or saline is injected to fill the lock. Interestingly, 0.9% sodium chloride has been found to be as effective as heparin and does not carry the minor risks associated with heparin. [26] [27] These catheter locks are safe, cost-effective adjuncts to ensure that practitioners have access to the patient's circulation when fluid administration or heparin is not indicated. [28] If a venous infusion is required, the hub of the saline lock may be punctured with an 18-ga needle.

In many institutions, "needleless" intermittent infusion devices, which use tubing and

replaceable caps, have replaced saline locks, which must be punctured with a needle. These devices are believed to decrease the chances of accidental needle sticks by medical personnel. Before inserting the IV catheter, the intermittent infusion device is flushed with saline, leaving 2 to 3 mL of saline in the attached syringe. The procedure for insertion of the IV catheter is the same. After the catheter is inserted and blood drawn, if indicated, the device is connected with a twisting motion until secure and is then flushed with the remaining saline. Then the syringe is disconnected, and a plastic cap is affixed using a twisting motion. A sliding clamp on the tubing is then pushed to occlude blood backflow or air embolism if the cap is removed for any reason. A major disadvantage to these infusion devices is that when using commercially prefilled syringes that have needles attached (e.g., for administration of cardiac resuscitation drugs), there is no rubber port to puncture so that medications can be injected. However, there are some devices that have injection ports and plastic caps, and these should be used in the emergency setting whenever possible.

After the indwelling catheter has been placed, an antibiotic ointment can be applied at the site of skin penetration (e.g., povidone-iodine or a multiple-antibiotic ointment such as polymyxin B-neomycin-bacitracin [Neosporin] or polymixin B-bacitracin [Polysporin]). An adhesive bandage or other sterile dressing (gauze pads or transparent polyurethane) is commonly placed over the puncture site, and the hub of the catheter and the IV tubing are then taped securely. Alternatively, a piece of ¼-inch tape, with the sticky side facing upward, may be placed under the hub and crossed in front of it, making an "X" (Fig. 20-9) . Clear polyurethane dressings allow direct examination of the site for signs of complications, such as thrombophlebitis and extravasation of IV fluid, and are used in many centers instead of tape (Fig. 20-10) . However, there is some evidence that plastic dressing has a higher incidence of phlebitis than gauze dressing. [29] After making a loop, the tubing should be taped down. This loop helps prevent the tubing or catheter from being dislodged accidentally if it is pulled. In many centers the dressing is dated, and the type and size of the catheter are recorded along with the practitioner's initials. As an additional measure, a short piece of stockinette or elastic netting can be applied over the insertion site and distal tubing to help prevent dislodgment.

**Percutaneous Brachial Vein Cannulation**

An alternative technique is percutaneous brachial vein cannulation. This technique is recommended for patients who

**Figure 20-8** Application of a saline lock. This was formerly called a *heparin lock,* but heparin is not required to keep the vein open; plain 0.9% saline will suffice as a flush. To convert this to an infusion site, puncture the rubber hub with an 18-ga needle. Blood may be drawn from the lock before beginning an infusion or flushing. If the lock contains saline, discard 3 to 4 mL of blood and wait 1 minute before collecting the sample.

**Figure 20-9** Securing the IV tubing. *A,* Placing the tape under the hub of the catheter, sticky side up. *B,*

Crossing the ends of the tape over the hub, forming an "X."

do not have easily accessible peripheral IV veins and is successful in 70% of cases. [15] [30] In one study, complications included transitory paresthesias in 18%, brachial artery puncture in 8%, and hematomas in 1.6%. [30] All of these complications were without long-term effects.

The practitioner first locates the brachial artery in the antecubital fossa by palpation. A tourniquet is then applied to the upper arm, and the skin is prepared as noted earlier. The brachial artery is again located, and a puncture site lateral or medial to the pulse is selected. The optimal side of the artery for use varies with the individual. An IV catheter attached to a syringe is advanced at a 30° to 45° angle to the patient's arm while the practitioner maintains suction on the syringe. After penetration of the vessel, the assembly is advanced 2 to 3 mm to ensure cannulation. The catheter is then advanced into the vein and secured. [15]

### Seldinger Technique

Occasionally a smaller gauge IV catheter (e.g., 20-ga) must be exchanged for one that is larger. This exchange can be made using the Seldinger technique (see Chapter 21) . This procedure may be necessary when other venous access sites are unavailable or more rapid access is required using a larger bore catheter. Such a catheter exchange set is made by Arrow, Inc. (product No. RC-09850). The site is prepared by swabbing povidone-iodine solution over the puncture site, indwelling catheter, and IV connector assembly. The administration tubing is disconnected from the indwelling catheter, and the flexible end of the guide wire is inserted through the lumen of the catheter. The catheter is then removed over the guide wire. The cutaneous puncture site is enlarged with a No. 11 scalpel blade, and a larger catheter is placed over the guide wire. The dilator is removed if a sheath-dilator assembly is used, and the catheter is checked for free-flowing blood. After successful cannulation, the catheter is attached to the IV tubing and secured.

## DIAGNOSTIC PHLEBOTOMY

Often the health care provider is unable to perform a diagnostic phlebotomy from a site away from the patient's IV line. This occurs when the patient has limited veins, multiple IV lines, amputated extremities, or relative contraindications such as mastectomy and renal shunts. In these situations, the practitioner must draw blood from the same extremity in which the IV line is placed. Phlebotomy can be done while the IV line is infusing if it is done *well below the infusion site.* [31] [32] This will not result in dilution of most serum chemistries; however, the serum glucose will be elevated if a glucose-containing solution is infusing. [31] A tourniquet can be placed in between the IV and phlebotomy sites for venous distention. [33] Blood can also be drawn directly from

the IV catheter after stopping the infusion and waiting for 2 minutes. [33] [34]

Another technique for diagnostic phlebotomy directly from the IV line has been described by Isaacson and colleagues. [32] The IV line is clamped above the injection port for 1 minute, and a tourniquet is applied above the IV site. A 10-mL Vacutainer tube and needle is inserted into the injection port, and 5 mL of blood is collected and discarded (Fig. 20-11) (Figure Not Available) . Uncontaminated blood should now be available

**Figure 20-11** (Figure Not Available) Drawing venous blood from an IV line. Contrary to the illustration, latex gloves should be worn; see text for details. Venous blood may also be drawn from a saline lock (see Fig. 20-8 ). *(From Isaacson G, Mansfield PF, Kirkland ML: An atraumatic technique for diagnostic phlebotomy. N Engl J Med 313:1478, 1985. Reprinted by permission of the New England Journal of Medicine.)*

for collection using the Vacutainer system. Tapping the vein at the catheter tip has been described as a method to restore blood flow by breaking away the seal between the vein and the catheter if the flow decreases. After collection of blood, the tourniquet and clamp are removed, and the tubing is flushed with a few milliliters of saline. Glucose and potassium levels may be elevated significantly by this technique if glucose- or potassium-containing solutions are infusing. Also if the tube is significantly underfilled, this can lead to a pseudometabolic acidosis.

## COMPLICATIONS

Complications of IV therapy may be local or systemic (Table 20-2) . Local complications include extravasation of fluids with local swelling, hematoma, phlebitis, cellulitis, and thrombosis. Hematomas are usually caused when the posterior wall of the vein is punctured during cannulation or after the cannula is removed. Bruising can be minimized in the antecubital fossa after venipuncture by leaving the elbow extended and applying direct pressure over the venipuncture site instead of flexing the elbow. [36] If the vein is not properly cannulated and there is resultant unrecognized SQ placement of the catheter and IV fluids are begun, the fluids will infuse into the tissues, causing swelling and pain. To avoid this, the

practitioner should be careful to observe for blood in the flash chamber on insertion; check the IV drip chamber for flow; and check the IV site periodically for swelling, pain, and tenderness.

Extravasation of irritants or medications can result in tissue destruction with resultant sloughing, thrombophlebitis, cellulitis, or venous thrombosis. If extravasation occurs, the cannula must be removed and replaced at another site as appropriate. [37] Significant skin sloughing that occasionally requires skin grafting may occur with the extravasation of certain medications, such as hypertonic solutions, vasopressors, and chemotherapy agents. Occasionally an "antidote" is available, such as in the instance of the extravasation of vasopressors, in which the resulting injury may be ameliorated by local SQ injection of phentolamine (Regitine) (Tables 20-3 (Table Not Available) , 20-4 (Table Not Available) , and 20-5) .

Phlebitis may occur in up to 75% of hospitalized patients. [27] The risk of phlebitis is

increased by infusion of irritant solutions, mechanical irritation from the catheter, infection, prolonged placement, catheter type (steel carries more risk than plastic), and large catheter size. [37] [38] [39] It is generally agreed that catheters should not be left in place for longer than 3 days because of the risk of a mechanical phlebitis. [1] [38] To identify infection or phlebitis, the insertion site should be checked daily for erythema, tenderness, and swelling. If inflammation is found, the IV catheter should be removed and a new catheter placed in another site. To avoid phlebitis or thrombosis from irritant medications, the medications should be dissolved in a large volume of fluid or administered through a central IV line.

Heparin and steroids may reduce the incidence of thrombophlebitis and may be useful in appropriate settings. [26] [40] [41] Buffering of acidic infusions with sodium bicarbonate may also reduce the incidence of phlebitis. [41] [42] Peripheral IV lines placed in the out-of-hospital care setting should be replaced when possible because of the high incidence of phlebitis when compared with the incidence associated with IV lines placed in the emergency department. [1] [43] [44] Therapy for noninfectious phlebitis includes moist heat, elevation of the extremity, and anti-inflammatory agents.

* Antidote administered either via the offending IV cannula or via multiple subcutaneous (SQ) injections with the catheter removed.

Occasionally patients present to the emergency department a few days after hospital discharge with the complaint of a hard knot or linear mass under the skin at the site of an IV infusion. A firm cord may be palpated, but the site should be neither tender nor red. Patients may believe that part of the IV catheter has broken off and remains under the skin. This is rarely the case. Most often the cord represents a venous thrombosis from irritating IV fluids and is generally a benign process. The patient should be reassured that although a blood clot may be present, it is not associated with pulmonary embolism. If a foreign body or infection can be excluded clinically, no intervention is required, and the condition will gradually resolve (over weeks) without significant sequelae, although the induration may never fully resolve in the vein. Radiographs are not indicated unless there is a history or examination that suggests an infectious process. The latter condition ( *suppurative phlebitis*) is generally associated with fever, local inflammation, and marked tenderness. The condition requires an aggressive interventional approach as outlined below.

Thrombosis can occur if IV fluids are allowed to run out or the saline lock is not flushed periodically. Infiltrated IV lines should not be irrigated because of the risk of central

embolism. [45] If infiltration occurs, a 3-mL syringe is connected to the cannula using aseptic technique and gentle aspiration is performed. If the return is bloody, discard the return and flush the catheter gently with 3 mL of sterile saline. The infusion is then resumed. If the return is not bloody, flush the catheter gently, as noted earlier. If resistance

is felt, the procedure is discontinued, and the catheter should be placed at another site. [46]

Nerve, tendon, or arterial damage may occur if these structures are directly punctured by the needle. [47] [48] [49] In addition, large hematomas may cause nerve damage and arterial insufficiency indirectly by compressing those structures and interrupting the blood supply.

*Suppurative phlebitis* is a rare complication and can result in sepsis and death. [50] This complication is suspected when phlebitis is associated with fever or purulent drainage. [50] Catheter-related infections of this type can be caused by the absence of aseptic skin preparation before cannula insertion, contaminated IV equipment, bacterial colonization, phlebitis, or contaminated infusate. [39] When these infections occur, any purulent drainage should be Gram stained and cultured, and the catheter tip should be sent to the laboratory to be cultured. Treatment includes removal of the catheter, administration of IV antibiotics and moist heat, elevation of the extremity, and venectomy.

Systemic complications include sepsis or embolism due to catheter, air, or clot. Bacteremia and sepsis can occur in 7% of patients with plastic catheters. [51] These infections are generally caused by common organisms such as *Staphylococcus aureus* and *Staphylococcus epidermidis.* [52] [53] As with noninfectious phlebitis, the incidence of catheter colonization and bacteremia increases significantly after 3 days. Hand washing and the use of aseptic technique on insertion (or system manipulation) and changing the IV sites every 3 days generally prevents this complication. Topical antibiotics such as povidone-iodine should be applied to the insertion site and may decrease the incidence of infection. [54] [55] [56] Despite earlier claims, frequent dressing changes are not necessary to prevent infection. In all cases, the site should be checked at least every 48 hours, and if infection or phlebitis is present, the catheter should be removed and placed at a new site. [56] [57]

Air embolism is a rare complication that occurs when air is introduced into the patient's bloodstream through the catheter, either through a syringe when improperly used to draw blood or more commonly through IV tubing when the container with IV fluids has been allowed to empty. Air embolism through an IV line is most common when fluids are delivered under pressure. Prevention is the key and is best done by ensuring the absence of air in the IV lines, keeping the IV container vertical during patient transfers, not allowing the IV containers to run dry, filling the drip chamber halfway before moving the patient, and paying careful attention to technique when changing tubing or

containers.

If air becomes trapped in the IV line, the least invasive method should be used to remove it. Boykoff and colleagues have described six ways to remove air from an IV line. [58] If the air is near the top of the IV line, it can be removed by holding the air-filled tubing taut and tapping on it with the finger. The air bubbles should rise into the drip chamber. Another technique is to curl a section of the tubing below the bubbles around a pen or syringe. The pen is then rolled upward toward the drip chamber, removing the bubbles.

If the bubbles are in the upper section of tubing, the bag can be lowered and the roller clamp opened to allow backflow of blood into the tubing. This may push the air back into the drip chamber. The Y connector can be used as a port from which to aspirate and is especially useful to

remove air found directly above the connector. To accomplish this, clamp the tubing below both the Y connector and the air. Clean the Y-connector port with 70% alcohol, insert a 10-mL syringe with a small-gauge needle into the port, and release the roller clamp. Aspirate the fluid and air into the syringe. The syringe is then removed, followed by the clamp. Using a similar technique, one can inject a sterile solution into the Y connector, pushing the bubbles into the drip chamber. This technique is especially useful if the drip chamber has collapsed. Finally, the tubing can be disconnected and flushed by opening up the rolling clamp. The IV tubing can be reattached directly to the catheter, or a heparin lock can be attached to the catheter and the IV tubing reattached using a sterile needle.

The use of in-line filters to prevent phlebitis is controversial. [59] [60] Filters are quite effective in removing particulate matter and reducing postinfusion phlebitis but are subject to filter clogging, air locking, and drug binding. [61] Drug binding is especially a problem when the amount of drug injected is small. In most cases, modern processing of parenteral materials, frequent changing of IV tubing and catheters, and the use of dilute solutions are effective in preventing phlebitis.

## CONCLUSIONS

The use of peripheral IV access, when performed correctly and appropriately, is easy and safe and may be life-saving, and it has few inherent disadvantages. It can be performed within minutes by any health care provider with minimal training.

### Acknowledgments

# Chapter 21 - Guide-Wire (Seldinger) Technique for Catheter Insertion

**Alfred D. Sacchetti**

The expedient placement of large-bore or central venous catheters can be a difficult task, especially in the unstable, critically ill patient. Frequently the physician is faced with the problem of being unable to locate a suitable vein or, more frustrating, being unable to cannulate a located vein. The guide-wire or Seldinger technique of catheter introduction is a valuable solution to vascular access problems in the emergency department.

The guide wire-through-the-needle technique was originally described in 1953 by Seldinger as a method for catheter placement in percutaneous arteriography. [1] The basic approach is simple and has been adapted for placement of devices in any hollow-lumen structure or body cavity. For vascular access, a small needle is used to enter the intended vessel. Once the introducing needle is positioned within the vessel lumen, a wire is threaded through the needle, and the needle is removed. The wire, which is now within the vessel, serves as a guide over which the selected catheter is placed.

## INDICATIONS AND CONTRAINDICATIONS

The primary advantage to the Seldinger technique of vascular access is that a relatively small needle can be used to place nearly any size or shape of catheter into a vessel. Table 21-1 lists the various sizes of vascular catheters along with the sizes of their introducer needles. A large 8.5 Fr high-flow infusion catheter or introducer sheath can be placed through a 22-ga puncture. This flexibility is of great value when attempting to place catheters in deep vessels, such as central veins. Subclavian, internal jugular, external jugular, brachial, femoral, and peripheral veins and arteries can all be cannulated using this technique. [2] [3] The use of the smaller introducer needle increases the probability of cannulating a hidden or collapsed vessel while theoretically reducing resultant injury should an adjacent structure, such as an artery or lung, be punctured.

Guide-wire approaches also allow for the rapid percutaneous placement of many catheters that might otherwise require a surgical procedure. A number of large-bore infusion catheters can be placed within the central circulation without the need for cutdowns of the femoral, saphenous, or brachial veins. [4] [5] In addition, this technique can be used to quickly convert small peripheral intravenous (IV) catheters to larger flow systems without the need for recannulation. [6]

Modifications of the guide-wire approach have expanded the indications for this technique beyond those of vascular access. Guide-wire systems exist now for almost every catheter system used in medicine. Table 21-2 presents a list of available guide-wire systems relevant to emergency medicine along with some of their manufacturers. The guide-wire technique is applicable to pediatric patients as well as

adults, and many commercial products are now available for use in children. The technique for placement is the same in children, only the size, and occasionally the composition, of the catheters differs.

The technique should not be used when large-bore catheter placement is not needed or may exacerbate hemorrhage. In general, patients receiving thrombolytic agents should not receive large-bore catheters.

## EQUIPMENT

The equipment needed for the guide-wire technique is listed in Table 21-3 . All of these items, with the exception of the needle, the wire, and the catheter, are part of the standard emergency department stock. The syringe in these systems should be a

non-Luer-Lok or slip tip type. The added twisting that is required to remove a Luer-Lok syringe from the introducer needle may actually dislodge a needle tenuously placed in a vein. Systems now exist in which the needle is modified to permit passage of the wire without removal of the aspirating syringe.

**Needle**

Virtually any needle or catheter can be used to introduce a guide wire into a vessel. The needle must be large enough to accommodate the desired wire. The needles contained in prepared sets are usually thin walled, and a smaller gauge can accommodate a larger wire. If a needle that is not thin walled is chosen, a size that is 1 ga smaller (larger bore) than that listed in Table 21-1 should be used. In standard peripheral IV systems that use a catheter-over-the-needle design, an 18-ga or larger-bore catheter will generally accept the standard guide wire that fits an 18-ga thin-walled needle.

The taper of the lumen at the proximal end of a specifically designed Seldinger needle is also different. Seldinger needles have a funnel-shaped taper that guides the wire directly into the needle (Fig. 21-1) . Ordinary needles may have a straight-bore lumen that leads squarely into the needle.

| TABLE 21-3 -- Necessary Equipment for Seldinger Technique | |
|---|---|
| Introducing needle | No. 11 scalpel |
| Guide wire | Lidocaine |
| Catheter or sheath introducer | 3-mL syringe (for anesthetizing) |
| Prep solution (iodine) | 3- to 5-mL syringe ( *not* Luer-Lok) |
| Sterile gloves | Suture (0-00) |

| | |
|---|---|
| Small anesthetizing needle (1.5 in., 25 ga) | Sterile drapes |
| | Antibiotic ointment |
| Gauze pads | |
| Prep razor | |

These needles can present a problem if the wire abuts the flat end-plate surface.

**Guide Wire**

Two basic types of guide wires are used: straight or J-shaped. The straight wires are for use in vessels with a linear configuration, whereas the J wires are for use in tortuous vessels. Both wires have essentially the same internal design (Fig. 21-2 (Figure Not Available) *A*). The flexibility of the wire is a result of a stainless steel coil or helix that forms the bulk of the guide wire. Within the central lumen of the helix is a straight central core wire, called a mandrel. The mandrel is fixed at one end of the helix and terminates between 0.5 and 3.0 cm from the other end. It adds rigidity to the portion of the wire surrounding it, whereas the remainder of the wire without the mandrel is the flexible or floppy end. Many guide wires also contain a straight safety wire that runs parallel to the mandrel to keep the wire from kinking or shearing.

Wires with two flexible ends contain the mandrel only in the central portion of the wire. In these systems one end is usually straight and the other end is J shaped.

The most common size for these wires is from 0.025 to 0.035 in. (0.064 to 0.089 cm) in diameter. Wire in this size range is generally introduced through an 18-ga thin-walled needle. A modification of this standard wire uses a bare mandrel with the flexible coil soldered to its end. This construction provides a wire with a diameter of only 0.018 in. (0.047 cm) but with the same rigidity as the larger wires. The manufacturer states that such a wire can be introduced through a 22-gauge thin-walled needle, yet still guide an 8.5 Fr catheter (Cook Critical Care Inc., Micropuncture Introducer Sets and Trays with Cor-Flex Wire Guides, Bloomington, Ind).

Wires may be coated with Teflon to reduce resistance or with heparin to inhibit clotting on wires left in place for extended periods.

The flexible end of the guide wire allows the wire to flex on contact with the wall of a vessel. If the contact is tangential, as in an infraclavicular approach to the subclavian vein, a straight wire is generally preferred. If the angle is more acute, as in an external jugular approach to the subclavian vein, or if the vessel is particularly tortuous or valves

must be traversed, a J-shaped wire is used. The more rounded leading edge of the J wire provides a broader surface to manipulate within the vessel and decreases the risk of perforation. This is especially advantageous when attempting to thread a wire through a vessel with valves.

It is important to emphasize that guide wires are delicate and may bend, kink, or unwind. A force of 4 to 6 lb may cause rupture of a wire. Embolization of portions of the guide wire is possible, and sharp defects in the wire may perforate vessel walls (see Fig. 21-2) (Figure Not Available) . One should carefully inspect wires for defects such as kinks, sharp ends, or spurs before use. [7] *Wires should thread easily and smoothly and should never be forced*

## Catheters

Once the guide wire is in place and the needle is removed, any number of catheter devices may be introduced. Single-, double-, and triple-lumen catheters are generally placed by sliding the catheter directly over the guide wire into the intended vessel. Larger catheters or non-lumen devices are generally introduced with a sheath-introducer system.

The Desilets-Hoffman type sheath introducer was designed by Desilets and Hoffman in 1965 to aid in arteriography procedures that required many catheter changes. [8] The sheath-introducer unit consists basically of two catheters, one inside the other (Fig. 21-3) . The first catheter, termed the *dilator*, is rigid; its inner lumen fits over the guide wire. This catheter is longer and thinner than its sheath and has a tapered end that serves as a dilator when the unit is passed through subcutaneous tissue and into the vessel. The dilator serves no other function than to facilitate placement of the sheath. The second catheter, termed the *sheath* (or *introducer* catheter when used as a cannula for introducing Swan-Ganz catheters, transvenous pacemakers, or other devices), has a

blunt end and is simply a catheter with a large diameter.

Many modifications of the sheath exist, with side arms and diaphragms to aid in placement of non-lumen devices. Care must be taken in the use of side-arm sets for rapid fluid administration, because some catheters may be 8.5 Fr in diameter but may have only a 5 Fr side arm. If faced with this problem, one can either remove the diaphragm or introduce an 8 Fr feeding tube through the diaphragm at the catheter hub for rapid fluid administration.

## PROCEDURE

The actual procedure for placement of Seldinger-type guide-wire catheters is quite simple. The vessel is first cannulated with a needle or an indwelling IV catheter. A guide wire is threaded through the needle or catheter and the needle or catheter is removed, leaving only the wire within the vessel. A catheter or introducer-sheath unit (often with a dilator) is passed over the guide wire through the skin and into the vessel. Once the introducer-sheath unit device is in place, the guide wire and dilator are removed. These steps are detailed in the following discussion.

**Guide-Wire Placement**

Sterile technique is maintained, bloodborne pathogen protection is taken, and the area of vascular access is prepared and cleaned.

An introducing needle or a standard over-the-needle catheter that is large enough to accommodate the guide wire is selected. The needle is attached to a small syringe (Fig. 21-4) . The needle and syringe are introduced together, and the selected vessel is cannulated. Once a free return of blood is obtained, the syringe is removed, and the needle is stabilized as it enters the skin to prevent displacement from the vessel. When cannulating a central vein, the needle hub is capped with a thumb before passing the guide wire; this minimizes the potential for air embolism. Next, the flexible end of the guide wire is threaded through the needle. If an IV catheter is already in place, the wire is simply passed through it and the catheter is removed.

The straight wire is easily introduced by threading the flexible end of the wire into the proximal hub of the indwelling needle. To introduce the J wire, a plastic sleeve contained in the kit is advanced to the floppy end of the wire to straighten out the J shape. This straightened end is then introduced into the proximal hub of the indwelling needle. Once the J wire has been advanced, the sleeve is removed

**Figure 21-3** Desilets-Hoffman sheath introducer. *A*, Guide wire. *B*, Sheath-introducer. *C*, Dilator. *D*, Assembled device.

and discarded (Fig. 21-5) . *Caution:* In an emergency this sleeve may be misplaced, making insertion of the J wire very difficult.

The wire should thread smoothly into the vein. If resistance is met, the wire should not be forced, but it should be removed from the needle and the syringe reattached to confirm intravascular placement. It is extremely important for the wire to slip easily from the needle during removal. If any resistance to removal of the wire is felt, *the wire and the needle should be removed as a single unit* to prevent shearing off of the wire. Despite its necessity, this last maneuver has occasionally been disregarded with resultant wire embolism. It is not that removal of both the wire and needle as a unit is technically difficult; rather, there is often reluctance on the physician's part to abandon a needle already in a vein.

Manipulation of the wire within an introducer needle should be done only with the standard coil wire guides. Manipulation should be avoided when using the solid wire sets in which the coil is soldered onto the mandrel. In these sets, the taper of the mandrel to the wire creates a very small lip that can become caught on the edge of the needle tip and shear off the coil portion of the wire. These wires must thread freely on the first attempt or the entire wire and needle assembly must be removed.

Some physicians recommend applying these restrictions to all guide wires and believe that no wire should ever be withdrawn through the introducing needle. [9] One method of avoiding this problem is to cannulate the vessel with a catheter-over-the-needle system and then use the soft catheter, rather than a sharp needle, as the entry source for the guide wire. The limitation of this approach is that the catheter itself cannot be advanced to relocate a vessel if the initial attempt at wire passage fails.

Occasionally, a wire must be teased into the vessel; rotating the wire or needle often helps in difficult placements. If the wire does not thread easily, another helpful maneuver is to pull back slightly on the needle itself just before advancing the wire. This helps if the opening of the needle is abutting the vessel's inner wall, blocking the wire's entry, or the vein is compressed by introduction of the needle. Changing wire tips from a straight to a J wire or vice versa also may solve an advancement problem. If the inner lumen of a vessel is smaller than the diameter of the J, it will prevent the wire from reforming its natural shape, causing the spring in the coil to generate resistance. Any advantages of a J wire will be negated if the wire fails to regain its intended shape. In this instance, a straight tip should be introducible without problems. Alternately, if the angle of entry of the needle and the vessel is more acute than was suspected, the straight wire may not be able to bend appropriately as it encounters the vessel's far wall. A J-tipped wire may be used and threaded in such a manner that the wire resumes its J shape away from the far wall. All of these maneuvers are performed with gentle free motions of the wire within the needle. If at any time the wire cannot be advanced freely, improper placement must be suspected and the attempt reevaluated.

If it is threading easily, the guide wire should be advanced until at least one quarter of the wire is within the vessel. The further into the vessel the wire extends the more stable its location when the catheter is introduced. Occasionally a wire threads easily past the

tip of the needle and then suddenly does not advance any farther. If the introducer needle demonstrated free blood return at the time of wire entry and the initial advancement of the wire met no resistance, the wire is most likely located properly in the vessel and can serve as a guide for the catheter. If further confirmation is needed, the needle may be removed, the wire fixed in place with a sterile hemostat, and a radiograph taken to confirm the position of the wire. [10] This confirmation may be advisable if the location of a wire is suspect and the introduction of a large-sized sheath is planned. A freely advancing wire may suddenly stop once it is well within a vessel if the vessel makes an unsuspected bend or is being compressed or deviated by another structure, such as a rib or muscle.

**Introducer Sheath Unit Placement**

Once the wire is placed into the vessel, the needle is removed and the desired catheter passed (see Fig. 21-4) . A small skin incision is made at the site of the wire. The incision should be approximately the size of the catheter to be introduced and should extend completely through the dermis. Precisely placing this skin incision directly over the wire entry site may be difficult if a small aspirating needle was used. Alternately, some physicians prefer to make the skin nick first and to introduce the needle through this incision. The disadvantage of this approach is that if the vessel is not where it is expected, the physician is forced to attempt a difficult entry through the existing incision or to make a second incision.

Once the incision is made, the introducer sheath with the dilator is threaded over the wire to a point 1 cm from the surface of the skin. The guide wire should be stabilized at the point of skin entry by the clinician during advancement of the introducer unit over the guide wire. *The wire must protrude from the back end of the introducer before advancement of the catheter past the skin*. This is a critically important procedural point. If the wire is not protruding from the proximal end of the introducer, it may be lost in the vessel and migrate to the central circulation. If the wire is not visible at the proximal end of the introducer, the introducer unit is not advanced until the guide wire is carefully withdrawn at the site of skin entry to the extent that it exits from the proximal end of the introducer unit. The wire must always be visible and graspable from the back end of the introducer throughout the remainder of the procedure. Guide wires are always longer than their catheters, and with experience it becomes easy to judge the optimal distance to thread the wire to ensure good introducer placement as well as to leave enough wire protruding from the proximal end of the introducer unit.

Once the wire is visible, it is grasped and held. The introducer unit is threaded into the skin with a twisting motion until it is well within the vessel. When using a sheath and dilator, it is best to grasp the unit at the junction of the sheath and dilator. This prevents the thinner sheath from kinking or bending at the tip or from bunching up at the coupler end. If a rigid-walled sheath is being used, the dilator need only be advanced a few centimeters into the vessel and the sheath slid off and advanced to its hub. If a thin-walled sheath is used, the introducer-sheath unit is kept intact and advanced through the skin to the hub. This adds rigidity to the sheath and prevents it from kinking before being fully seated in the vessel. In placing right-sided subclavian catheters, it is sometimes helpful to make a banana-like bend in the dilator before introduction to

facilitate proper location in the superior vena cava. [11] Once the introducer unit is in place, the wire and dilator are removed together. Precautions are again taken to cover the sheath hub to avoid air embolism after removal of the wire and dilator before attachment of the infusion tubing or cap. Once in place, the device is usually affixed with 1 or 2 sutures, and infusion or monitoring is begun.

If a single-lumen catheter is used instead of a sheath-dilator, the catheter itself is passed over the wire to its desired depth and the wire is removed. When a soft catheter is used, a tract from the skin to the vessel must be created before the catheter can be introduced. This tract is created by passing and removing a separate dilator over the guide wire after the needle is removed but before the catheter is placed. After the dilator is removed the soft catheter is threaded into the position over the wire. Occasionally, it is easier to advance the soft catheter over the wire up to the skin edge and then to advance the catheter and wire together as a unit into the vessel. As always, it is imperative that the guide wire protrude from the back of the catheter and be firmly grasped when the wire and catheter are being advanced.

To place multiple lumen catheters, the distal lumen and hub are identified. The distal lumen is the hole at the tip of the catheter. At the proximal end of the device, the hub that corresponds to the distal lumen will be labeled "distal" by the manufacturer. If there is any confusion, a small amount of sterile saline can be injected through each hub until it is observed coming out of the hole at the tip of the catheter. Once the distal hub is identified, its cover cap is removed to allow the guide wire to pass through. The catheter is placed by threading the guide wire into the hole at the tip of the catheter and advancing it until it is visible and graspable at the hub end of the device. At this point the device is placed in the same manner as a single-lumen catheter. If a soft

multiple-lumen device is placed, a separate dilator is used to create a tract over the guide wire *prior* to placing the catheter. An alternate method of placing multiple lumen catheters is to thread the catheter through a standard Desilets-Hoffman sheath introducer system.

Any lumen in a multiple-lumen device that is not immediately used for an infusion must be flushed with a heparin solution. Saline solutions alone should not be used as flushes for central catheters. When removing the wire from a catheter it must slip out easily. If any resistance is met, both the wire and catheter must be removed as a single unit and the procedure reattempted. A common cause of a "stuck wire" is a small piece of adipose tissue wedged between the wire and the lumen of the catheter. This problem can be avoided by creating a deep enough skin nick and adequate dilation of the tract before insertion of the catheter.

**Replacement of Existing Catheters**

In addition to placing new catheters, the guide-wire technique can be used to change existing devices. The utility of this technique in converting a peripheral small-gauge catheter to a larger infusion catheter is obvious. Within a few seconds, an existing peripheral or central 18-ga IV catheter can be changed to an 8.5 Fr infuser. The guide-wire technique can also be used to change single-lumen central venous catheters

to triple-lumen or sheath-introducer sets. In these instances a guide wire longer than either of the devices to be exchanged is selected. It is inserted into the existing central venous catheter until approximately a few centimeters are protruding and are graspable from the proximal end. With one hand holding the wire securely, the catheter and wire are removed as a single unit until the tip of the catheter just clears the patient's skin. The wire is grasped at the point at which it exits the skin, and only then is the other end of the wire released. The catheter is then slid off the wire, and the new device is inserted in the normal fashion. Caution must be exercised with this technique because catheter embolization can occur if a catheter is cut to allow use of a shorter guide wire for the exchange. [9] In patients without evidence of sepsis, the technique of guide-wire exchange does not increase the incidence of catheter-related infections. However, in septic patients this maneuver does appear to increase infections related to central catheters. [12]

**Modifications of Guide-Wire Catheter Systems**

Modifications of the basic guide-wire technique have been developed to permit easier wire placement into the introducing needle. Self-contained systems are available in which the wire is introduced through a side sleeve in the needle or through a central hole in the aspirating syringe (e.g., Safety Syringe, Arrow International, Inc, Reading, Pa). Another variation of this system maintains the in-line wire introduction while aspiration is done though a small tube and side port of the needle. Such systems are designed to permit a more rapid or reliable placement of the wire once the vessel is cannulated. Although quicker, these devices sacrifice operator sensitivity in teasing difficult wires into place.

The guide-wire technique is readily adapted to placement of catheters in any body cavity. The technique used in these situations is identical to that for vascular access, except that blood is not aspirated through the introducing needle. If a technique requires aspiration of air (e.g., puncture of the cricothyroid membrane), it is helpful to partially fill the aspirating syringe with sterile saline. When the trachea is entered, bubbles will appear in the syringe as the air is aspirated. Other situations in which a wire-guided technique is used include intra-abdominal abscess drainage, peritoneal lavage, percutaneous nephrostomy and cystostomy, cricothyrotomy, pericardiocentesis, tube thoracostomy, and retrograde endotracheal intubation. [13] [14] These procedures are discussed more fully elsewhere in the text.

# COMPLICATIONS

Vascular access using the guide-wire technique has gained wide acceptance in emergency and critical care units. Any complication inherent in the performance of central or peripheral vascular access with other systems may also occur with this technique. Intuitively, the smaller needles used with the guide-wire technique should produce fewer complications than the larger needles used in the catheter-through-the-needle systems. However, the only comparison study between these two techniques failed to demonstrate any significant decrease in complications with the guide-wire technique. [15] Yet, in another study in which only the guide-wire technique was used, few complications were noted in central venous catheter

placements. [16] Other reports have shown quicker access or higher success rates with wire-guided techniques compared to standard or cutdown approaches. [5] [17] [18]

Some complications unique to guide-wire use may occur. Wires have been reported to form knots or to perforate vessels if forcibly introduced. Experience has shown that the wire will indeed kink or separate when ego exceeds wisdom and removal of the wire from a catheter, rather than removal of the two as a unit, is forcibly attempted. If kinking occurs, whatever portion of the system that contains the wire should be removed along with the damaged wire.

Lost wires have embolized when the technique was not performed correctly (e.g., the wire was not grasped at all times or was forcibly removed from an introducer needle). If embolization occurs, the procedure should be stopped and radiographs obtained to localize the wire. Portions that embolize into the central circulation must be removed using some form of retrieval device in an angiography suite.

Lost wire fragments that are subcutaneous and are easily palpated may be fixed in place by application of direct pressure just proximal to the location of the piece. Once the wire is immobilized it may be removed like any other palpable foreign body. Wires that cannot be felt but can be seen on x-ray in the area of the attempted catheter placement are best removed surgically with fluoroscopic assistance. Patient movement should be minimized to prevent more proximal migration of the wire during preparations for surgery.

On occasion, wire fragments can be isolated in an extremity by placing a tourniquet proximal to the wire. This will prevent any central migration until surgical removal is performed under fluoroscopy.

The use of the guide-wire technique also has allowed the introduction of a number of new catheter styles, each with its own complications. Multi-lumen central venous catheters tend to be larger and stiffer than their single-lumen

counterparts, making them more likely to cause vessel perforations. In addition to size, the configuration of the catheter affects its tendency to perforate. A model comparing the relative perforating potential of various catheters revealed that pigtailed or flexible-tipped catheters were less likely to perforate a simulated vessel wall than were straight catheters. [19]

Sheath introducers also have demonstrated some unique complications. Thin-walled sheaths may collapse or crimp from external tissue pressure or from being forced into a severe bend. This is not a problem if the sheath is being used to introduce a pacemaker, but if it is being placed for fluid resuscitation, its efficacy decreases markedly. Newer devices with internal supports or flexible sections avoid this problem and allow much greater freedom in the bending of the sheaths.

Another complication of such devices concerns the adaptors used to seal the proximal ends. Because of the large size of these catheters, the chance for air entry into the system is greater if the caps or diaphragms are not fitted properly. Air leakage and

actual air emboli have been reported to result from improperly sealed devices.

**CONCLUSION**

The development of the guide-wire technique for catheter placement has made possible a simple, rapid, percutaneous system for entry of almost any desired vessel or cavity. Because it can be learned quickly and it presents minimal complications, this approach is well suited to emergency and critical care vascular access.

# Chapter 22 - Venous Cutdown

**Steven C. Dronen** , **Patricia Lanter**

"The standard cutdown is well known to all trauma surgeons and needs no description." [1] Were this a true statement, the remainder of this chapter would be superfluous; however, physician training in the technique of venous cutdown has been largely informal. For 4 decades, the mechanics of venous cutdown have been handed down from house officer to house officer as one of the rites of internship. There are, in fact, few detailed descriptions of the procedure in the medical literature, and the scientific data documenting its usefulness or complication rate are sparse.

An early description of the technique of venous cutdown was provided in 1940 by Keeley, who offered the procedure as an alternative to venipuncture in patients in shock or in individuals with small, thin veins. [2] In 1945, Kirkham gave the first detailed description of the saphenous vein cutdown at the ankle. [3] Although the article is somewhat dated, most of the steps remain unchanged.

The most significant changes over the past 4 decades have involved not the technique itself, but the cannulas that are used. Keeley and Kirkham used metal needles. With the advent of plastic cannulas in the mid-1940s, the cutdown became more popular as a means of providing long-term IV infusion. Physicians have used IV tubing, feeding tubes, and even nasogastric tubes as cannulas in the management of hypovolemic patients. Currently, large-bore catheters (10-ga, 8 Fr) are often inserted by cutdown in the management of hypovolemic shock. [4]

The frequency with which the venous cutdown is performed is impossible to estimate. The growing popularity of central venous cannulation by the internal jugular, subclavian, and femoral routes has most probably decreased the frequency of venesection. Nevertheless, the cutdown remains

an excellent method of obtaining venous access in several emergent clinical situations. Although a cutdown is mechanically simple to perform, ease of performance does not guarantee that the procedure will be performed efficiently and without complications. Performance of a rapid, effective cutdown can be achieved only by thorough knowledge of the procedure and attention to its many details.

## INDICATIONS

There are no absolute indications for venous cutdown, simply because several options for venous access usually exist. The indications for use of the procedure are relative, depending to a great extent on physician experience and preference. There are several clinical situations in which the venous cutdown may be used.

**Venous Access in Infants**

Small children present a unique challenge to the clinician who does not perform pediatric venipuncture regularly (see Chapter 18) . The challenge is greater still if the procedure must be performed rapidly in a child or infant in shock or in a child in whom few, if any, veins are visible. Other options frequently used include intraosseous infusion or cannulation of the femoral, subclavian, or internal jugular veins. In selected circumstances (e.g., status epilepticus), the rectal route of administration, with mucosal absorption, is an effective alternative to cutdown.

A venous cutdown may be performed when all accessible peripheral sites, including scalp veins, have been exhausted. The distal saphenous vein is large enough to cannulate in most children and has a predictable anatomic location. Therefore, venous cutdown at the ankle is commonly used for both emergent management and long-term venous access. [5] [6]

**Hypovolemic Shock**

Rapid percutaneous insertion of large-bore (14-ga) catheters is appropriate in most cases of hypovolemic shock. Unfortunately, peripheral vessels frequently collapse in hypovolemia or have been rendered useless by IV drug abuse or previous venous catheterization. The venous cutdown is an acceptable alternative in these instances, although percutaneous insertion of a large-bore introducer device into a central vein can usually be performed more rapidly. When the cutdown can be performed quickly, it offers the advantage of direct visualization of the vessel during cannulation.

The use of the cutdown as a vehicle for the insertion of IV extension tubing and rapid transfusion was made popular during the Vietnam war. [7] The technique also has been found useful in civilian practice for the resuscitation of patients with profound hypovolemia. [8] The flow rate for saline through a standard IV extension set (3 mm inside diameter) cut to a length of 28 cm (12 inches) and inserted directly into the vein is 15 to 30% greater than that through a 5-cm, 14-ga catheter. The difference is greater if pressure is applied to the system. The improvement in flow rate through large-bore lines is greater for blood than for crystalloid solutions, because the viscous characteristics of blood greatly impede its passage through small-bore tubing. [8] [9] A unit of blood can be transfused in 3 minutes using IV extension tubing inserted into the vein. Consequently, large-bore lines placed by venous cutdown are an excellent mechanism for the treatment of severe hypovolemia. High-flow infusion techniques are discussed further in Chapter 23 .

# CONTRAINDICATIONS

Venous cutdown is contraindicated when less invasive alternatives exist or when excessive delay would be required for the procedure to be performed. [10] Although highly skilled operators may perform a cutdown in <60 seconds, [11] studies by Rhee and colleagues [12] and Iserson and Criss [13] have shown that, on average, the procedure requires 5 to 6 minutes to complete. Percutaneous insertion of large-bore catheters is the preferred method of rapid fluid infusion unless high flow rates are required or

peripheral vessels have collapsed. Another method of rapid fluid infusion that is technically easier and faster than venesection is the percutaneous insertion of large-bore introducer devices into the subclavian, internal jugular, or femoral veins (see Chapters 21 , 23 , and 24) . These devices typically use 8 Fr catheters with flow rates comparable to those obtained with IV tubing. The use of the subclavian and internal jugular vessels also is preferable to the cutdown for long-term applications.

Other contraindications are relative. In the presence of coagulation disorders, impaired healing, or compromised host-defense mechanisms, the need to perform a cutdown should be weighed carefully against the potential complications. Cutdowns should be avoided when there is an infection over the site and in extremities with injuries proximal to the cutdown site.

## ANATOMY

Detailed knowledge of anatomy is imperative to the success of this procedure. Veins in both the upper and lower extremities may be used. The choice of a particular vein should be governed by its accessibility and size and by the physician's experience and training. The anatomy of individual vessels and their relative merits as cutdown sites are described in the following paragraphs.

**The Greater Saphenous Vein**

The greater saphenous vein is the longest vein and runs subcutaneously throughout much of its course (Fig. 22-1) . It is most easily accessible at the ankle but may also be cannulated below the knee and below the femoral triangle. The greater saphenous vein begins at the ankle, where it is the continuation of the medial marginal vein of the foot. The vein crosses 1 cm anterior to the medial malleolus and continues up the anteromedial aspect of the leg. [14] At the level of the malleolus, the vein lies adjacent to the periosteum and is accompanied by the relatively insignificant saphenous nerve, which if transected causes sensory loss in a small area along the medial aspect of the foot. At the ankle, the vessel can be exposed with minimal blunt dissection. The vein's superficial, predictable, and isolated location has made the distal saphenous vein the classic pediatric cutdown site. [15]

The saphenous vein lies superficially on the medial

**Figure 22-1** Superficial veins of the lower limb.

aspect of the knee. A cutdown performed 1 to 4 cm below the knee and immediately posterior to the tibia has been described in the pediatric literature. [5] This site is distal enough to avoid interference with the performance of other resuscitative procedures, yet proximal enough to allow the passage of a long line into the central circulation. [16] However, it is seldom used for venous cutdown. Disadvantages of this site include kinking of the line as the knee is flexed and the risk of injury to the saphenous branch of

the genicular artery and the saphenous nerve. [17]

In the thigh, the saphenous vein begins on the medial aspect of the knee and crosses anterolaterally as it ascends toward the femoral triangle. Proximally, it enters the fossa ovalis and joins the femoral vein. Three to 4 cm distal to the inguinal ligament, the saphenous vein is of large caliber (4 to 5 mm outside diameter) and is easily isolated from the surrounding fat. Also lying anteromedially in the thigh is the lateral femoral cutaneous vein, which has a smaller diameter (2 to 3 mm) and lies lateral to the greater saphenous vein. [18] [19] The accessibility and large diameter of the greater saphenous vein in the thigh make its use an option in the treatment of profound hypovolemia. [8]

**The Basilic Vein**

The basilic vein is a preferred site for venous cutdown in the upper extremity. Veins of the dorsal venous network of the hand unite to form the cephalic and basilic veins, which travel along the radial and ulnar sides of the forearm, respectively (Fig. 22-2) . At the level of the mid-forearm, the basilic vein crosses anterolaterally and is consistently found 1 to 2 cm lateral to the medial epicondyle on the anterior surface of the upper arm. The medial cubital vein crosses over from the radial side of the arm to join the basilic vein just above the medial epicondyle. The basilic vein then continues proximally, occupying a superficial position between the biceps and pronator teres muscles. In this segment it lies in close association with the medial cutaneous nerve, which supplies sensation to the ulnar side of the forearm. The vein penetrates the brachial fascia in the distal third of the upper arm and then occupies a deeper position. [20]

The basilic vein is generally cannulated at the antecubital fossa 2 cm above and 2 to 3 cm lateral to the medial epicondyle. It is exposed through a transverse incision on the medial aspect of the proximal antecubital fossa. The size of this vein enables it to be located easily, even in the hypotensive or hypovolemic patient; large catheters can generally be passed without difficulty. The median cubital vein is accessible through the same incision. Superficially at this level, there are no important associated structures, but the brachial artery and the median nerve are found deep to the basilic vein.

A more proximal insertion site has been recommended by Simon and colleagues [21] to avoid the network of interconnecting veins at the level of the antecubital fossa. However, in the distal third of the upper arm, there is a closer association between the basilic vein and the medial cutaneous nerve. Transection of this nerve produces sensory loss on the ulnar side of the forearm.

**The Cephalic Vein**

This vessel begins on the radial aspect of the wrist and crosses anteromedially, ascending toward the antecubital

**Figure 22-2** Veins of the upper limb.

fossa. In the forearm it lies in close association with the lateral cutaneous nerve, which supplies sensory innervation to the radial aspect of the forearm (see Fig. 22-2) . In the antecubital fossa it lies subcutaneously, just lateral to the midline, and then ascends in the upper arm, overlying the lateral aspect of the biceps muscle. At the shoulder the cephalic vein lies in the deltopectoral groove. Just below the clavicle, it passes deep to end in the axillary vein. [20]

Venesection is easily performed on the cephalic vein because of its large diameter and superficial location. In the forearm it is important to avoid the lateral cutaneous nerve. A good location is in the antecubital fossa at the distal flexor crease. Cutdown on the cephalic vein at the wrist has also been reported, [22] but the thin skin overlying the vein at this level usually permits simple percutaneous cannulation when the vein is available for cannulation. The cephalic vein may also be entered in the deltopectoral groove. The slightly deeper position and physical interference with the performance of other procedures make this approach more difficult.

### The Brachial Veins

The brachial veins are small, paired vessels lying on either side of the brachial artery. In contrast to the vessels described earlier, these are not superficial and will not accommodate large cannulas. Their most superficial location is 1 to 2 cm above the antecubital fossa just medial to the biceps muscle. Palpation of the brachial pulse serves as a useful landmark. Because of its proximity, the brachial artery may be inadvertently cannulated in the pulseless patient. In addition, there is the risk of injury to the closely associated median nerve. Time-consuming blunt dissection is usually required because of the vessels' greater depth. For these reasons, brachial vein cutdown is *not recommended* as an emergency venous access route [10] and should be used only in the absence of a suitable alternative. This site may be acceptable when time and vessel size are not critical factors, but it is difficult to justify the deep dissection and associated risks that are involved.

### The External Jugular Vein

The external jugular vein begins below the angle of the mandible and is formed by confluence of the posterior auricular and retromandibular veins. It descends posterolaterally across the surface of the sternocleidomastoid muscle and then pierces the fascia to join the subclavian vein deep to the clavicular head of this muscle. The greater auricular nerve, which supplies sensation to the external ear, travels parallel to the external jugular vein. [14]

A venous cutdown may be performed on the external jugular vein at its superficial location on the sternocleidomastoid muscle. This is not recommended as a first-line means of venous access for the following reasons:

1. Performance of a cutdown may cause physical interference with airway management and central venous cannulation.

2. There is risk of injury to the greater auricular nerve.
3. It is difficult to immobilize the area adequately.
4. Cervical spine immobilization frequently prohibits access to the area.
5. It is a hazardous procedure in the uncooperative patient. [10]

As a general rule, cutdown on the external jugular vein should be performed only when other means of venous access are exhausted. The external jugular vein is an acceptable site for emergency *percutaneous* venous cannulation, especially in children.

## EQUIPMENT

The materials required to perform a formal venous cutdown are listed in Table 22-1 . All necessary instruments should be available on a sterile tray before the procedure is begun. The standard cutdown tray is shown in Figure 22-3 . A time-consuming search for the proper instrument can be avoided if only necessary instruments are included on standardized trays. Pediatric patients also require both a warming table or radiant warmer and a padded extremity board.

Catheter choice depends on the desired function of the venous line. When central venous pressure (CVP) monitoring is needed, the catheter chosen must be long enough to reach the superior vena cava. The average distance from the antecubital fossa to the superior vena cava is 54 cm in the adult male. This distance can be approximated by aligning the catheter over the chest with the tip at the level of the manubrial-sternal junction. Lumen size is relatively unimportant when the line is inserted for monitoring the CVP or to infuse drugs, but it is a critical factor in the treatment of hypovolemia. Short, large-bore catheters are preferred when fluid must be delivered rapidly. Silastic catheters, IV plastic tubing, or 5 or 8 Fr pediatric feeding tubes may be used as infusion catheters in older children and adults.

Tables 22-2 (Table Not Available) through Tables 22-4 (Table Not Available) list the flow rate of various fluids through some commonly used catheter systems. Knowledge of relative flow rates is essential if maximal benefit is to be obtained from the time spent performing the cutdown. Excellent flow rates can be achieved by threading IV tubing (sterile tubing may be cut to the appropriate length) directly into the vein or by using a 5 cm, 10-ga IV catheter.

## TECHNIQUE

The technique of venous cutdown is essentially the same regardless of the vessel cannulated (Figs. 22-4 through (Figs. 22-13

**TABLE 22-1** -- Materials Required for Venous Cutdown *

Detailed knowledge of the local anatomy is important if the procedure is to be performed rapidly without injury to associated structures. Adequate immobilization on a padded board should be accomplished prior to beginning the procedure. This is especially important in children (see Fig. 22-13) . Even in emergency situations, reasonable precautions should be taken to avoid infection. The area of the skin incision should be widely prepared with an antiseptic solution and then draped. A tourniquet placed proximal to the cutdown site helps in the visualization of the vein.

In the conscious patient, the site is infiltrated with 1%

**Figure 22-4** A skin incision is made perpendicular to the course of the vein.

lidocaine. A skin incision is made transverse to the course of the vessel (see Fig. 22-4) . A longitudinal incision may decrease the risk of transecting neurovascular structures but does not provide sufficient exposure. A transverse incision involving all layers of the skin is the best approach. Subcutaneous (SQ) fat should bulge from the incision. The clinician bluntly dissects SQ tissue by spreading the tissue gently with a curved hemostat *in a direction parallel to the course of the vein.* Bleeding is usually minimal unless the vein is nicked. A tissue spreader or a self-retaining retractor may be used to provide a wider field. The vein is then isolated from the adjacent tissue and mobilized for 1 to 3 cm (see Fig. 22-5) (Figure Not Available) .After the vein is mobilized, a hemostat can be used to pass proximal and distal silk ties under the vein for stabilization. An alternative approach is to simply use the hemostat tips (with no ligatures) in a "spread" position to elevate and stabilize the exposed vein during incision and cannulation. The hemostat is placed as in Fig. 22-7 (Figure Not Available) , only without taking the time to pass ligatures.

If ligatures are passed prior to cannulation, the distal ligature may or may not be tied after initial placement. If the distal ligature is tied, it should not be cut, because the proximal tie is useful in controlling the vein (see Figs. 22-6 (Figure Not Available) and 22-7) (Figure Not Available) . Using a hemostat, the vessel is elevated and stretched flat. This provides good visualization and control of the vessel and limits bleeding when the vessel is incised. Alternatively, placing gentle traction on the proximal tie will control

oozing around the puncture site. The vessel is incised at a 45° angle, through one third to one half of its diameter (see Fig. 22-7) (Figure Not Available) . A No. 11 blade (as illustrated) or a pair of iris scissors may be used to incise the vessel. Too small an incision may cause threading of the catheter into a false channel in the adventitia; conversely, the vessel may be torn completely and may retract from the field if the incision is too large. [23] A longitudinal incision is sometimes made to avoid transecting the vessel, but the lumen is more difficult to identify with this technique. *The vessel incision must enter the actual lumen of the vein*, although some bleeding will occur after the vein has merely been nicked. Incision of the vessel is unnecessary when an IV catheter with an introducing needle is used. The vessel is simply punctured, as in percutaneous venous cannulation (see Mini-cutdown).

Before being introduced into the vessel, the cannula is beveled at a 45° angle unless a cannula with a tapered tip is used. A short bevel is preferred, and a sharply pointed tip is to be avoided, because it may pierce the posterior wall or otherwise damage the vein. The rounded tip of a feeding tube may be more difficult to introduce, but it may be advanced less traumatically. If using an IV cannula, the cannula may be introduced directly through the skin incision or through a separate stab wound. The latter method, using an Intracath device, is illustrated in Figures 22-8 (Figure Not Available) and 22-9 (Figure Not Available) . Theoretically, the percutaneous approach reduces the risk of infection. [24] Threading the catheter into the vein is often the most difficult and time-consuming portion of the procedure.

Difficulty in threading may be encountered for several reasons. The lumen may have been incorrectly identified, or a false passage may have been created. This frequently occurs and may be difficult to recognize, because the catheter can easily advance between layers of the vessel wall. Other causes of difficult threading are penetration of the posterior vessel wall, the presence of venous valves, or use of a catheter that is too large for the vessel being cannulated. Identification of

**Figure 22-13** The cutdown site is securely dressed and splinted.

the vessel lumen may be facilitated through use of a plastic venous dilator or elevator. The small, pointed tip of the device is threaded into the vessel to expose the lumen in advance of the catheter (see Fig. 22-10) . A sterile 20-ga needle bent at a 90° angle may also serve as a vein elevator. A vein dilator is useful in pediatric cutdowns but is generally unnecessary in adults. The clinician can facilitate the threading of large catheters in adults by grasping the proximal surgical edge of the vessel with small forceps or a mosquito hemostat. Counter traction is applied as the catheter is advanced (see Fig. 22-11) . At no time should one force a catheter that will not advance.

Once the catheter is advanced into the lumen, air is back-bled from the cannula, and the cannula is connected to IV tubing. The proximal ligature is tied around the vessel wall and the intraluminal cannula. The tourniquet is now removed, the catheter is affixed to the skin, and the incision is closed (see Fig. 22-12) . An antibiotic ointment is applied at the point at which the catheter passes through the skin, and the wound is dressed. In an emergent situation, skin closure can be delayed and the wound simply wrapped with a

sterile dressing (e.g., Kerlix) (see Fig. 22-13) . The IV tubing should be looped under the outer layers of the dressing to minimize the risk of inadvertent removal of the cannula should the external IV line be tugged.

## Mini-Cutdown

An alternative method designed to preserve the vein and bypass the time-consuming step of placing a catheter into the vessel has been described. [25] A skin incision and blunt dissection are used to locate the vessel. Once identified, the vein is punctured under direct vision with a standard percutaneous venous catheter. Alternatively, a large-bore introducer device with or without a dilator can be threaded over a guide wire using this technique. The needle may be introduced through a separate stab incision or through the skin incision. If an over-the-needle device (e.g., Angiocath, Medicut) is used, the needle is withdrawn and discarded. With a through-the-needle device, the cannula is threaded into the vein, and the needle is withdrawn to the skin surface (Fig. 24-14) (Figure Not Available) . A guard is placed on the needle tip, the

**Figure 22-14** The mini-cutdown technique is an alternative to the venous cutdown method. The vein is cannulated under direct vision using standard percutaneous catheters. A separate entry site (shown) may be used, or the vein can be cannulated through the skin incision. Note that the vein is not tied off with this technique. A standard Angiocath IV set also may be used instead of the through-the-needle catheter shown here.

catheter device is fixed to the skin, and the incision is closed. This method eliminates the need for tying or cutting the vein, thereby permitting repeated catheterization. Venipuncture is easier and uses the same equipment as for percutaneous venous cannulation. The mini-cutdown is therefore used in the treatment of chronically ill patients who require long-term IV therapy or in children who have limited accessible veins. A simple skin incision may also permit direct visualization of veins in the obese patient and may facilitate standard percutaneous venipuncture.

Hansbrough and coworkers [4] described the mini-cutdown procedure with a 10-ga IV catheter (Deseret 10-ga Angiocath). The flow rates of blood and saline with this catheter are equal to the rates obtained when IV extension tubing is placed in a vein using the more time-consuming standard venous cutdown technique. This catheter allows one to infuse a unit of whole blood in 2 to 3 minutes if pressure and oversized IV tubing (e.g., urology irrigation tubing) are used.

Shockley and Butzier describe a further modification whereby the guide wire technique is modified by passage of the guide wire, dilator, and sheath system following standard cutdown and venotomy. [26] They found this technique to save more than 2 minutes' time over the standard technique when performed by novices.

Removal of catheters inserted by cutdown requires only cutting of the skin stitches

holding the catheter in place, followed by withdrawal of the catheter. Backbleeding from the proximal venous end is controlled by a simple pressure dressing and is generally not a significant problem.

## COMPLICATIONS

The complications of venous cutdown include local hematoma and infection, sepsis, phlebitis, embolization, wound dehiscence, and injury to associated structures. An indirect but significant complication is deterioration of an unstable patient during a time-consuming cutdown attempt. Documentation of complications and their frequency has been sparse. Bogen reported a 15% complication rate in 234 cases. [27] Infection and phlebitis each occurred at a rate of 4%. Infectious complications may result from the introduction of pathogens during line placement, transcutaneous invasion along the course of the cannula, or deposition of blood-borne organisms on the catheter tip. [28] A clear correlation exists between the incidence of infectious complications and the length of time that a catheter is left in place. Moran and associates found that the infection rate rose from 50 to 78% when a catheter was left in place for more than 48 hours. [29] Druskin and Siegel, studying a mixed population of patients who had undergone cutdowns and others who had catheters percutaneously inserted, found that the incidence of culture-positive catheter tips rose from 0 to 52% after 48 hours. [28] In the study by Moran and colleagues, *Staphylococcus albus* was the predominant organism that was isolated, but organisms more commonly thought of as pathogenic ( *S. aureus*, *Enterococcus* spp., and *Proteus* spp.) were isolated with greater frequency from cutdowns that had been in place for long periods. [29] Rhee and colleagues reported a 1.4% infection rate (one episode of cellulitis) following 73 cutdown attempts. [12] All catheters were removed within 24 hours.

There is some evidence that the rate of infectious complications decreases when a broad-spectrum antibiotic ointment is applied to the cutdown site. Moran and coworkers found a rate of infectious complications of 18% when topical polymyxin B-neomycin-bacitracin (Neosporin) was used, compared with a 78% rate in a placebo-treated group. [29] In this study, it was also shown that topical antibiotic use results in only a moderate decrease in the incidence of phlebitis (from 53 to 37%) but a significant decrease in the incidence of phlebitis associated with positive cultures (from 86 to 14%). This suggests that phlebitis is primarily a chemical or an irritative process rather than the result of infection. [29] Whatever the cause, the incidence of phlebitis is clearly related to the duration of catheterization. [7] [27] [30] Early catheter removal is a key factor in the prevention of both phlebitis and the infectious complications of venous cutdown. This is especially true of lines inserted during emergency resuscitative treatment. Such lines should be removed as soon as the patient's condition stabilizes and alternative routes exist. [8] [10]

Proper attention to the details of surgical technique will limit the occurrence of minor complications, such as local hematoma, abscess, and wound dehiscence. One can avoid injury to associated structures by selecting a site in which the vein is isolated and specifically avoiding brachial vein cutdown.

# Chapter 23 - High-Flow Infusion Techniques

**Kenneth V. Iserson**

High-flow infusion techniques date back to the Vietnam War era. During that period, surgeons placed intravenous (IV) tubing directly into veins to facilitate rapid high-volume infusions. Rapid isotonic volume resuscitation following hemorrhage has been promoted as a means to minimize shock-related organ injury and death. [1] Recently, laboratory [2] [3] and clinical investigations [4] have raised concern that overzealous volume resuscitation of patients with penetrating trauma prior to definitive control of hemorrhage may increase hemorrhage volume and mortality. However, similar laboratory studies have demonstrated that delayed volume resuscitation is associated with increased metabolic acidosis. [5] Regardless of the optimal timing for fluid resuscitation (i.e., either "as soon as possible" or "after control of hemorrhage"), high-volume techniques remain an important therapeutic intervention for patients with significant volume deficits.

A difficulty in describing high-flow techniques is that there has been a progressive increase in flow rates in what is described as "high-flow." Whereas 1 L/hour of isotonic fluid was at one time considered a rapid infusion, isotonic fluids can now be placed through peripheral IV lines into normovolemic adults with commercially available equipment at rates exceeding 800 mL/min. [6] "High-volume" infusion of crystalloids may be set arbitrarily at 500 mL/min. Massive transfusion of blood has been traditionally defined as transfusion of an amount at least equal to the recipient's blood volume within a 24-hour period. [7] However, with commercially available equipment, the in vitro flow rate of admixed erythrocytes can exceed 800 mL/min through one line. [8] One case has been reported of a patient surviving after having received more than 12 units of blood product per hour for 30 hours.

## IMPORTANCE OF TECHNIQUE

Clinicians often have little time in which to restore effective circulating intravascular volume in patients who have had acute loss of volume (e.g., through traumatic or nontraumatic hemorrhage or from septic or anaphylactic shock). In patients who have lost large volumes of fluid in the period of minutes, as is seen with acute injury and illness, high-flow infusion techniques are often used.

Hypovolemic shock also results in an increase in intravascular capacity, requiring much more IV fluid to be infused than the volume of blood lost. [10] At some point in resuscitation, sufficient intravascular volume (preferably with adequate oxygen-carrying capacity) to supply nutrients for cellular metabolism must be restored. Those techniques of rapid high-volume infusion that can be used successfully with only one large-bore IV line in place gain added significance in situations in which multiple lines can be established only with difficulty (e.g., in patients with severe shock, a history of IV drug abuse, fragile veins, massive swelling, or obesity).

## ROLE OF HIGH-FLOW INFUSION

High-flow infusion may be used by all clinicians, paramedical personnel, and nurses who treat critically ill patients. Trauma patients, patients with gastrointestinal bleeding, and those in septic or anaphylactic shock are prime candidates. The techniques involved are relatively easy to learn, and the equipment is both inexpensive and similar enough to that already being used for standard IV fluid therapy that no major barriers should exist to using high-flow techniques when indicated.

Some of the techniques, especially those using the automated external pressurization devices, reduce the time needed for personnel to infuse fluid by conventional IV techniques (Table 23-1) (Table Not Available) . [12] Large (12- or 10-ga) peripheral IV catheters are not much more difficult to place than the 14- or 16-ga catheters that are routinely recommended. In the pediatric population, a venous cutdown, whether to directly insert IV tubing or catheters, requires a significant amount of time and skill. [13] Although venous cutdown lines (see Chapters 18 and 22) can be used in conjunction with high-flow infusion systems, cutdowns are not addressed further in this chapter.

## INDICATIONS AND CONTRAINDICATIONS

The primary indication for high-volume infusion is hypovolemic shock. Although the infusion may be needed only for a short period until vital signs stabilize, preparations are often made for the necessary equipment to be available "on standby" in case the patient's condition deteriorates again.

Often it is unclear initially whether the patient requires high-volume resuscitation. Despite historical evidence suggesting massive volume loss, patients may be hypotensive for other reasons or may arrive in a volume-resuscitated condition after a prolonged transport with associated volume administration. If any doubt exists regarding the need for high-volume infusion, short, rapid boluses (10 to 20 mL/kg) of fluid can be given and the patient repeatedly reassessed.

The goals of shock resuscitation are to minimize further volume loss and to maintain organ perfusion until the shock-induced pathophysiologic state can be reversed. In hemorrhagic shock, control of ongoing blood loss is essential. When the blood loss is internal, excessive volume resuscitation accompanied by elevation of blood pressure may exacerbate the blood loss preoperatively. The classic clinical example of this phenomenon is the patient with a leaking aortic aneurysm. Hence volume resuscitation must be closely monitored.

Rapid high-volume infusion is relatively contraindicated in cases of neurogenic shock following trauma. Because the hypotension of neurogenic shock is not due to hypovolemia, hemodynamics do not improve with administration of large amounts of fluid. Rather, the fluid often collects in the patient's lungs and leads to pulmonary edema. Patients who can be recognized as having hypotension that is due to a pericardial tamponade may do well with administration of small, rapid boluses of fluid

until a pericardiocentesis or definitive repair is performed, but large volumes of fluid do not appear to be beneficial. Patients whose hypotension is not due to hypovolemia (e.g., those with pump failure or impaired venous return) can be harmed by the fluid overload that would accompany a rapid, high-volume infusion.

# EQUIPMENT

The key to performing effective rapid infusion therapy and to obtaining the proper equipment is to consider the entire infusion system, rather than just the individual parts. Each

part of the infusion system must be able to meet the desired flow and time requirements (see Table 23-1) (Table Not Available) .

Unfortunately, IV catheters with "exactly the same measurements" can deliver fluid at surprisingly different rates. [14] (Note in Table 23-1 (Table Not Available) that three different manufacturers make 14-ga 2-in. catheters, and the flow rates by gravity range from 93 to 134 mL/min.) Therefore, when choosing an IV system for an emergency department, it should be tested to ensure that the system and all components perform as advertised.

## Catheter

Fluid flow through a tube, as in the case of an IV catheter, generally behaves in a fashion described by Poiseuille's law:

With all elements of a high-flow infusion system, it is the internal diameter (ID) that is overwhelmingly important in determining flow rates. The ID affects flow rates to the fourth power, whereas all other elements affect flow only to the first power. Therefore, to obtain a maximal flow rate, the goal is to optimize the ID of all parts of the system. For example, more rapid infusion can occur by increasing the diameter (smaller gauge) of one IV catheter than by starting a second line with another small-ID catheter. [15]

Although some very large experimental catheters, exceeding 4.5 mm (14 Fr) ID, have been developed and used successfully for infusions in humans, [16] [17] large, commercially available percutaneous IV catheters have a maximum ID of 2.16 mm (12 ga, Vygon Mosquito 123) or 3 mm (9 Fr). [14] Swan-Ganz introducers are not tapered and have a very thin-walled construction. Because they are designed to accommodate the size catheter for which they are labeled, the labeled size is usually their ID.

Flow resistance in a tube is inversely proportional to tube length. However, even with long IV catheters, the ID is much more important for determining flow resistance than catheter length. Catheter length is significant primarily because the catheter must be long enough to mechanically remain in place within the vascular space. Theoretically, an IV catheter for rapid fluid replacement should have its maximum ID maintained throughout its length. This means not only that the main portion of the catheter should have a maximum ID consistent with structural stability, but also that the reduction in ID

from narrowing at the catheter tip should be minimal. Some catheters lose more than 36% of their ID in this taper.

Choosing an intraosseous infusion site constitutes a major exception to using the catheter ID to extrapolate the resultant flow rate. Even when large-ID catheters are placed, the resistance to flow out of the intraosseous space appears to limit rapid, high-volume infusion at this site.

**Intravenous Tubing and Extension Tubing**

Poiseuille's law applies to IV tubing as well as to indwelling catheters. Most standard IV tubing for blood transfusions has an ID of 3 mm. [6] [18] Larger tubing is now available, some with an ID of 3.66 (11 Fr) to 4.0 mm. A more recent development is the Medex Hi-Flow Trauma Quad System tubing, with an ID of 5.7 mm. Although this large-bore tubing can sustain flows of more than 1 L/min of admixed blood, it essentially ceases to function because of obstruction of its own filter after 3 units of packed cells have been infused. This problem can be overcome successfully by using an in-line Pall filter. [8]

Using even the 3.66-mm tubing can increase flow rates of saline from 70% (12-ga catheter, pressurized) to 126% (8 Fr catheter, no pressure) over rates with the 3-mm tubing. [6] A comparable difference would be expected with blood products.

Even if large-diameter IV tubing is used, adding a smaller-sized extension tubing can reduce the ID of the system enough to make this element the rate-limiting step, negating the benefit of the other components of the system. If large-ID IV tubing is used, it is essential that similarly sized extension tubing also be available. Improving the efficiency of the drip chamber also would improve flow, but little progress has been made so far in this system component. [15]

Even when crystalloid is infused, all IV tubing must be of the "Y"-type. That is, there must be at least two attachments for IV bags. This feature allows one bag to be changed while the other is infusing. At the flow rates achieved by rapid high-flow systems, not having Y-type tubing will normally cut the overall system infusion rate by at least half. Y-type tubing is also necessary to admix blood with warmed saline, as described later.

**Solution Container**

All fluids used in the resuscitation of hypovolemic patients are now available in compressible, soft plastic containers. The more rigid plastic and glass containers should be avoided, because they are much more difficult to externally pressurize in the former case and present the danger of breaking in the latter case. To conserve the number of bag changes that personnel have to perform, a time-consuming element of infusion, 1-L bags are preferable to smaller sizes for the adult patient. Blood, generally in the form of packed red blood cells, is packaged in standard plastic containers that can accommodate up to 600 mL of fluid (see Blood Warmers).

**External Pressure Device**

Pressurizing the fluid that is being infused increases the fluid flow rate dramatically. [6] [11] Traditionally, clinicians have tried to pressurize IV fluid systems bags by manually squeezing them, kneeling on them, using blood pressure cuffs around them, and using commercial pressure devices. Only manually squeezing the bags or using commercial pressure devices is effective. [19]

The most practical means of adding pressure to a high-flow IV system is through the use of external pressure devices (Fig. 23-1) . The standard maximal external pressure exerted by these units is 300 mm Hg. Until recently, most centers were still using pneumatic pressurization devices, with the inflow and outflow of air being controlled by a screw-down mechanism--the blood pump. [20] This device is not only cumbersome but also unreliable in either maintaining pressure or releasing pressure so that a new bag of fluid or blood can be placed. [12] More recently, somewhat less expensive pressure bags with 3-way stopcocks have become available.

**Figure 23-1** Three types of external pressure devices. *A*, Infuser-1. (As modified in Iserson KV, Reeter A, Woods W, Criss E: Pressurization of IV bags: A new configuration and evaluation for use. J Emerg Med 3:89, 1985.) *B*, Infusable (Biomedical Dynamics Corp., Minneapolis). *C*, Alton Dean infuser (North Salt Lake City, Utah).

These appear to be easier to use but still have the problem of not maintaining a constant pressure on the fluid while the bag empties. Some pressure bags (Infusable, Biomedical Dynamics Corp., Minneapolis) are considered to be disposable, even though many uses can be obtained from each unit.

Other, more elaborate external pressure devices also have been advocated, including blood pumps attached to a constant air-pressure source. [21] More recently, these pressurization devices not only have been powered by wall air, but also have been contained in a rigid metal or plastic container for safety, more rapid access, and extremely rapid pressurization and depressurization (Infuser-1 and Alton Dean Infuser, North Salt Lake City). These devices have the advantage of maintaining a constant pressure on the fluid container during emptying. It has been shown that using the air-pressure devices dramatically decreases the time needed for changing bags during infusions (Table 23-2) (Table Not Available) , thus enhancing the effective flow rate during high-volume infusion situations. [12] [22]

Some initial work has been done with devices that exert a higher external pressure on the fluid containers. Pressures of 600 mm Hg have been obtained. As expected from Poiseuille's law, the larger the ID of the tubing and catheters in the system, the greater the increase in flow rate achieved with increased pressure. Although this high pressure does not damage the equipment, it is unclear whether blood cells can be damaged at this pressure. [11]

**Blood Warmers**

In nearly all high-volume infusions, blood products are administered. This poses the problem of infusing blood products at or around 4 °C (the temperature at which blood is stored) or using a blood warmer in the system. Rapid infusion of cold blood is associated with an increase in ventricular fibrillation and cardiac arrest. [23] [24] Hypothermia is a major, yet often unappreciated, problem during the resuscitation of seriously ill patients, particularly those who require multiple blood transfusions. [25] Blood warmers heat blood either before the infusion (prewarming) or during the infusion (in-line). Most commonly available warmers are the in-line type, and most of them significantly slow the flow rates of high-flow systems. [24] [26] [27] Some blood warmers have been developed that have more rapid flow rates, but these are not readily available. [28]

One proposed method for keeping flow rates high while warming blood to approximately body temperature is to dilute the blood with an equivalent volume of 70 °C saline. [29] [30] [31] [32] This technique, because of the rapid equilibration of temperatures between the two mixing fluids, does no damage to the erythrocytes. Of course, because of the resulting warm temperature of the blood (approximately 37 °C), it must be infused rapidly. In addition, *the 70 °C saline must never be used for direct infusion* (Fig. 23-2) .

One commercial system combines warmed saline at 45 °C with cold blood in a single pressurized mixing bag and delivers the admixed solution through a high-flow infusion set (Sangui-Stat System, Ackard Laboratories, Cranford, NJ). This system is designed specifically for the rapid warming and transfusion of packed erythrocytes in the emergency department, although the resultant temperature is below body temperature and will contribute to hypothermia with large-volume infusions (Fig. 23-3) (Figure Not Available) .

**Fluids**

Although a great deal of experimental work has been done to compare lactated Ringer's solution and normal saline in hypovolemic resuscitation, the solutions seem to be equivalent in clinical settings. The application of small-volume hypertonic saline in the resuscitation of patients in hypovolemic shock is promising, but use of this fluid continues to be experimental. [33] [34] [35]

When transfusing cellular blood products rapidly, it is essential not only to warm the fluid but also to dilute it adequately to reduce the incidence of erythrocyte hemolysis. Cellular destruction in blood flow systems is directly proportional to the magnitude of shear stress and cellular-solid surface interactions. These are affected directly by hematocrit and plasma protein concentration. The greater the dilution of the blood product, the less hemolysis. [36] [37]

**System Perspective**

Although new equipment items continue to be developed to assist in high-volume infusion, all items are limited by the same essential principle--the minimum ID of the system must be as large as possible. [16] [17] Equipment that only offers increased pressure, decreased setup and takedown time, or decreased system tubing length should be accompanied by an appropriately large system ID.

## PROCEDURE

### General Concepts

Usually the most difficult part of initiating a rapid, high-volume fluid system is ensuring adequate preparation through in-service training of physicians and nurses, stocking essential components, and setting up the components to be used. The equipment should be located conveniently close to the patient and within reach of the practitioners.

Given appropriate preparation, the next difficulty is establishing IV access with a large-bore catheter. Catheter placement should proceed with the largest size catheter that can be quickly placed. Even if only a small-bore catheter can be placed initially, a larger catheter often can be inserted through this catheter using the Seldinger technique (see Chapter 21) . Furthermore, alternative sites can be sought for a larger-bore catheter as volume resuscitation begins through a smaller-bore catheter. Ideally a 10- or 12-ga, 9 Fr, or larger catheter is placed in either a peripheral or femoral vein. Central veins about the neck should be avoided if possible, because extravasation with rapid flow rates may lead to a large hematoma and possible airway obstruction.

Once one or more catheters are in place, large-bore Y-type tubing, no less than 3.66-mm ID, should be attached. If an extension tube is needed, it must have at least as large an ID as the rest of the tubing. Prewarmed 1-L bags of crystalloid solutions (ideally at 37 °C) should be initially hung in an external pressure device. Either an easily used manually operated pressure bag (Infusable, Biomedical Dynamics Corp, Minneapolis) or a wall-operated pneumatic device (Infuser-1 and Alton Dean Infuser, North Salt Lake City) is acceptable.

When erythrocyte units are available, they should be diluted 1:1 with 70 °C preheated 0.9 N saline. ( *Note:* Do not use lactated Ringer's solution.) When performing this procedure, use a special system (e.g., Fenwal plasma transfer set, No. 4C2243, Fenwal Laboratories, Deerfield, Ill) to guarantee that the hot saline will not be directly infused into the patient. [32] [38] Many types of laboratory incubators can be used for preheating the saline. A constant temperature monitor should be available to ensure adequate heating. According to tests by the manufacturer, bacterial growth within the unopened heated saline units should not occur for at least 2 weeks if the units are left in their overwrap packaging. [29] When the 1:1 dilution is used, the admixed blood is then at approximately 37 °C and ready for rapid infusion. Mistakes may be minimized by preheating only one particular-sized bag (250 mL is appropriate and usually the right amount for diluting the erythrocyte unit) and premarking the bags for dilution with bright orange or yellow tape. Heated saline bags should be discarded if not used after 2 weeks

to avoid chemical leaching from prolonged heating. [38]

If a rapid-infusion system is used in one part of an institution, it is essential not only that other interactive units (e.g., the operating room and intensive care unit) be made aware of it, but also that any equipment that the other units use in managing critical care patients be compatible with that used for rapid infusion in the emergency department.

**Vascular Access Sites Affecting Flow In Vivo**

The limitation to placing large venous catheters in an adult or a larger child is generally the skill of the operator. Any

large peripheral or central vein is large enough to accommodate very large catheters, with the natural distention that occurs. There is virtually no obstruction to flow from any anatomically intact venous site. [17] However, placing catheters in veins distal to an area of vascular injury, such as in a lower extremity in a patient with abdominal bleeding, may limit the usefulness of the fluid resuscitation.

**Intravascular Volume Affecting Flow In Vivo**

It does not appear that intravascular pressure significantly limits the flow rate of rapid-infusion IV fluid. Although the estimated backpressure is 15 to 18 mm Hg in supine, normovolemic males, this seems to decrease the in vitro flow rates only by a negligible 5 to 6%.

## COMPLICATIONS

The complications of high-volume infusion usually are related to one of three problems:

1. The catheter may be in the wrong location so that large amounts of fluid enter into a closed space, such as the chest or pericardium, with untoward effects. Rather than being resuscitated by the rapid fluid infusion, the patient deteriorates as a result of, and in proportion to, the amount of fluid infused.
2. Too much fluid is inadvertently and unknowingly infused. Unfortunately, there is no totally satisfactory way to monitor intravascular volume in the acute setting, and excessive fluid resuscitation is surprisingly easy. Close attention to vital signs, pulmonary status, and urine output is important. When available, central venous pressure monitoring or, preferably, Swan-Ganz

   catheter monitoring may be used, but these are generally available in the acute resuscitation setting.

3. Problems occur related to massive blood transfusions. The major and most immediate problems relate to hypothermia (with resultant dysrhythmias) and coagulopathies. These may be mostly ameliorated with the use of warmed blood and the timely use of fresh frozen plasma (see Chapter 29) .The complication rate

for high-volume fluid therapy in patients with severe hypovolemia is unknown. The patient's condition, "hypovolemic shock," usually implies a poor outcome from the start. Limited information on massive, rapid fluid boluses in otherwise healthy animals suggests that there are few problems that do not resolve once the infusion is stopped. [39] However, in the injured patient, cellular changes accompanying injury (e.g., pulmonary, neurologic) may not allow reversal of fluid-induced changes as easily. Further, concerns have been raised that over-resuscitation may exacerbate hemorrhage through a variety of mechanisms. [2] [3] [4] If a patient is believed to have been overloaded with fluid, normal techniques to reduce the amount of fluid (e.g., stopping the infusion, using diuretics, and appropriately using cardiovascular or respiratory support) should be instituted.

## INTERPRETATION

Success with rapid IV infusion techniques is often fleeting. Often the goal is only to buy enough time to institute definitive operative intervention. Interpretation of fluid resuscitation, at least at the present time, is largely clinical. Evaluation of the entire clinical picture, including vital signs, urine output, peripheral perfusion, and mentation, is necessary to determine the success of infusion therapy. Occasionally, of course, when a thoracotomy has been done, direct observation of the central circulation allows an accurate determination of the state of vascular filling.

With rapid infusion consisting primarily of crystalloid solutions, patients sometimes have enough blood loss to leak "water" from bleeding sites. This is essentially a visual manifestation of an extremely low hematocrit and indicates a nearly hopeless prognosis. Otherwise, hematocrit measurements are virtually useless in assessing the intravascular status of unstable patients. Some patients, especially younger ones, continue to have enough vascular tone to appear to stabilize after an initial large bolus of fluid. These patients must be carefully observed and evaluated, because their condition can deteriorate again without warning.

## CONCLUSION

Unfortunately, success with rapid, high-flow IV infusion does not guarantee a successful outcome for the acutely ill patient. Further, in the emergency department or out-of-hospital setting, it is often impossible to assess the severity of injuries. Therefore, rapid, high-flow infusion therapy should be considered in conjunction with other therapies when seriously injured patients remain hypotensive and display clinical signs of shock despite delivery of oxygen, ventilation, and a modest volume challenge.

# Chapter 24 - Central Venous Catheterization and Central Venous Pressure Monitoring

Steven C. Dronen, John G. Younger

## Central Venous Catheterization

The popularity of central venous access has paralleled the medical advances of recent years and is increasingly part of patient care in the emergency department and intensive care setting. Advanced monitoring techniques, transvenous pacemakers, and parenteral nutrition all require rapid, reliable methods of central venous access. Peripheral venous sites can be used for some of these procedures, but use of peripheral sites requires long catheters that must be threaded accurately into the superior or inferior vena cava. Peripheral veins may be collapsed, thrombosed, buried in subcutaneous (SQ) tissue, or otherwise difficult to locate. Several large veins, including the subclavian, jugular, and femoral, have predictable relationships to easily identified landmarks and can be cannulated within minutes. Consequently, large vessel venipuncture has become a common practice in a variety of clinical settings, and it is a technique with which all physicians involved in the care of acutely ill patients should be comfortable.

### BACKGROUND

Subclavian venipuncture was described by Aubaniac in 1952, and its use was promptly supported by others. [1] [2] [3] Wilson and colleagues described the role of central venous pressure (CVP) monitoring in the maintenance of optimal blood volume and are credited with popularizing subclavian venipuncture in the United States. [4]

Numerous reports of clinical experience with the infraclavicular (IC) subclavian technique followed Wilson's article. These stressed the clinical usefulness of the procedure, the ease with which it is performed, and its low complication rate. Subclavian venipuncture was described as useful in the management of hypovolemia, burns, cardiac arrest, chronic IV therapy, and septic shock. [5] [6] [7] [8] [9]

Early enthusiasm for subclavian venipuncture was eventually tempered by a growing awareness of serious and occasionally fatal complications. [10] The reported complications of the IC approach suggested the need for a safer method. In 1965, Yoffa described the supraclavicular (SC) approach with its more direct approach to the subclavian vein and low complication rate. [11] Dronen and associates compared the 2 approaches during the performance of cardiopulmonary resuscitation (CPR) and found a significant decrease in catheter tip malposition and CPR interruption when the SC approach was used. [12]

An early mention of the internal jugular (IJ) approach was in a pediatric handbook by Silver and coworkers in 1963. [13] An IJ approach in the adult (with what later became known as the *central approach*) was described by Hemosura in 1966. [14] Subsequently a variety of approaches were described, ultimately to be grouped into the anterior,

central, and posterior approaches by Defalque in 1974. [15]

These techniques, as well as the femoral and cephalic-basilic approaches, have a place in the practice of emergency medicine, and often the choice of a particular approach is determined solely by the confidence of the individual physician in his or her ability to use the approach. In general, success rates are higher and complications less frequent when these techniques are used by more experienced technicians. [16] Although every clinician has a preferred method for achieving central venous access, any physician caring for critically ill patients should master several of these techniques.

## INDICATIONS

There are several commonly encountered clinical situations in which central venous access is indicated. If necessary, any central venous approach can serve the following functions. However, experience suggests that certain approaches offer advantages over others in most clinical settings. Advantages and disadvantages of each technique are outlined in Table 24-1 (Table Not Available) and discussed in detail after the general indications.

### Central Venous Pressure Monitoring

Although supplanted to a great extent by more sophisticated and accurate methods, particularly right heart catheterization with a balloon-tipped pulmonary artery catheter, CVP measurement remains a useful tool in the treatment of selected hypovolemic patients.

| **TABLE 24-1** -- Advantages and Disadvantages of Central Venous Access Techniques *From Knopp R, Dailey RH: Central venous cannulation and pressure monitoring. JACEP 6:358, 1977.* |

| (Not Available) |

### Volume Loading

Subclavian venipuncture has been widely used as a vehicle for rapid volume resuscitation. Unfortunately, it is often misused in this regard. The flow rate of saline through a peripheral 5-cm, 14-ga catheter is roughly twice that through a 20-cm, 16-ga central venous catheter, with equivalent pressure heads. [17] The difference in flow is

even greater for blood products because of higher viscosity, which slows the passage of red cells through small-gauge catheters. [18] Consequently, the placement of peripheral large-bore catheters is the preferred method of rapid volume loading, unless time would be lost searching for a venipuncture site or unusually large volumes need to be infused.

Use of a large-bore (8 Fr) introducer catheter overcomes the impairment of flow seen with standard central venous catheters. Introducers offer flow rates that exceed even those of common IV tubing. [19] In trained hands this is a useful method of rapid fluid resuscitation, although it is associated with significant risk if the catheter is misplaced. Dutky and colleagues note that kinking of introducer catheters may halve their flow rate. [20] They found that kinking is common when long introducer catheters are placed via the IC route at the junction of the medial and middle thirds of the clavicle.

**Emergency Venous Access**

The predictable anatomic location of the subclavian, jugular, and femoral veins and the speed with which they can be cannulated (usually in 15 to 30 seconds) have prompted their use in cardiac arrest and other emergency situations. Although subclavian venipuncture by the IC route is an ideal means of rapid venous access, it may not be the best technique to use during CPR. Chest wall motion and physical interference with the performance of effective CPR make IC venipuncture more difficult and perhaps more dangerous in this setting. [12] The need for a central line during CPR is controversial, although many clinicians advocate use of a central line routinely. It has been suggested that therapeutic drug levels are reached more rapidly if given centrally. [21] [22] When easily obtained, central venous cannulation is preferred over peripheral venous access, because it provides a rapid and reliable route for the administration of drugs to the central circulation of the patient in cardiac arrest.

**Routine Venous Cannulation**

Drug abusers, burn victims, and obese or long-term care patients may have inadequate peripheral IV sites. Subclavian vein cannulation may be indicated under these circumstances.

**Routine Blood Drawing**

The potential complications of central venous cannulation do not justify its use in routine blood sampling. Lines already in place may be used for this purpose if they are properly cleared of IV fluid. A 20-cm, 16-ga catheter contains 0.3 mL

of fluid, so at least this much must be withdrawn to avoid dilution of blood samples. Because of the increased risk of infectious complications, air embolus, and venous backbleeding, the IV tubing should not be repeatedly disconnected from the catheter hub. Interposition of a three-way stopcock in the IV tubing simplifies access and is an acceptable method of blood sampling in the intensive care setting.

**Hyperalimentation**

In 1969, Dudrick and colleagues described the beneficial results of long-term parenteral nutrition in patients with various gastrointestinal disorders. Hyperalimentation by way of the subclavian vein was found to be safe and reliable. [23] Use of the IC technique frees the patient's extremities and neck; this procedure is therefore well suited to long-term applications. However, strict aseptic technique is necessary to minimize infectious complications. [24]

**Infusion of Concentrated Solutions**

Hyperosmolar or irritating solutions that have the potential to cause thrombophlebitis if given through small peripheral vessels are frequently infused by way of the subclavian vein. Examples are potassium chloride (>40 mmol/L), hyperosmolar saline, chemotherapeutic agents, and acidifying solutions, such as ammonium chloride.

**Other Indications**

Other indications for central venous access include placement of a pulmonary artery catheter or transvenous pacemaker, performance of cardiac catheterization and pulmonary angiography, and hemodialysis. Catheters such as the Uldall device can be inserted within minutes, permitting use of the subclavian vein for emergency or short-term hemodialysis. [25]

**Relative Indications for Different Approaches**

**Subclavian approaches.**

The IC subclavian approach is the most frequently used means of central venous access and is useful in most clinical settings. However, it is associated with a slightly higher incidence of complications. The SC approach is an important alternative to IC venipuncture, particularly in the setting of cardiac arrest. During CPR, the SC approach is often preferred because it minimizes physical interference with the functions of chest compression and airway management. The IC approach requires deep penetration of a moving chest wall and frequently demands an interruption of chest compression. An SC subclavian venipuncture can be performed without cessation of CPR and involves superficial penetration of the relatively motionless neck. [12] The technique also avoids interference with airway management, which commonly occurs when the internal jugular vein is cannulated. [26] When a true central venous location is required, the SC approach is superior to the IC and long peripheral line insertion techniques because of the low incidence of catheter tip malposition with the SC approach. [27] In addition, the SC technique has been performed in the sitting position in patients with severe orthopnea. Placement of a central line with the patient in a sitting position is virtually impossible with other central venous access routes. [28] Finally, the low complication rate reported for SC venipuncture makes it a more attractive alternative, especially in the seriously ill patient.

[26] [27] [28]

**Internal jugular approach.**

As is true of the SC subclavian approach, the IJ technique is useful for routine central venous access and for emergency venous access during CPR, since the site is removed from the area of chest compressions. [29] Comparison of IJ and subclavian cannulation has found a significantly greater incidence of proper venipuncture and catheter passage with the IC subclavian approach as compared with the posterior IJ method (98% vs 84%). [30] A 20% rate of catheter malposition was noted with each method. In 1 retrospective study, only 0.4% of 248 IJ cannulations resulted in clinically significant morbidity, compared with 4.2% of 298 subclavian insertions, even though the overall complication rate was similar. [31] Although there may be a slight difference in complications between the 2 routes, in the absence of specific contraindications, the physician should use the technique with which he or she is most familiar. The IJ route is slightly more technically difficult than the subclavian route but is faster and easier than a venous cutdown.

**Femoral approach.**

The cannulation of the femoral vein for central venous access has become increasingly popular in the last several years, especially for the passage of transvenous pacemakers and pressure measurement catheters in critically ill patients. [32] Mangiante and associates have had such success with femoral catheters for trauma patients that they have recommended that all hypotensive patients have a femoral line established with an 8.5 Fr Teflon catheter connected to genitourinary irrigation tubing immediately after 2 peripheral antecubital catheters are established. [33] They report no significant iliofemoral thrombosis, major hematoma, or infectious complications due to catheters. Other indications for urgent femoral cannulation include emergency cardiopulmonary bypass for resuscitation purposes, charcoal hemoperfusion for severe drug overdoses, and dialysis access. [34] Advantages of the femoral site over other central venous access sites are that the femoral area is less congested with monitoring and airway equipment than the head and neck area and that the conscious patient, who is still bedridden, may turn the head and use the arms without movement of the central line. Obviously, the femoral site is contraindicated in the ambulatory patient who requires central access.

**Other approaches.**

In instances where other methods of central venous catheterization are not possible, one may obtain access to the central venous circulation via the external jugular (EJ) vein or basilic-cephalic vein. [35] [36] Although generally accessible for peripheral IV access, the valves and tortuousity of these veins often preclude or delay placement of standard central venous catheters. Successful cannulation of the central venous circulation is generally possible only with the use of guide wires. The EJ vein must be visible for percutaneous cannulation to be successful. When time is available for a careful, deliberate attempt, these methods avoid the complications of pneumothorax, carotid or subclavian artery puncture, and hidden hemorrhage associated with other

methods of central venous cannulation.

The EJ approach can be used in both children and adults, but success is more common in adults. [36] [37] Central venous catheterization by the EJ route is technically more difficult than IJ cannulation, but it is successful 70-100% of the time in adults. [38] While use of a straight guide wire has been described, the use of a J wire is more reliable and is the preferred method. [37] The J wire is more easily advanced because its round tip bounces off vessel walls and navigates sharp angulations in the vessel course more easily.

When rapidity of access to the central venous circulation is not important, the basilic-cephalic route should be considered. This route has the lowest incidence of complications since the basilic and cephalic veins are located far away from vital organs and major arteries. When the patient is upright, the basilic vein is preferred over the cephalic vein because of a higher incidence of successful central catheter passage, although the overall success rate of superior vena cava cannulation is similar for both techniques in the supine patient. [39] Nonetheless, both veins have valves, which may impede catheter advancement. [40]

## CONTRAINDICATIONS

Contraindications to the various techniques of central venous access are shown in Table 24-2 . Most listed contraindications can be considered relative with clinical use of these techniques based on clinical conditions and available options for vascular access. Each technique in general is contraindicated in patients with distorted local anatomy or landmarks. Skin lesions such as local cellulitis, burns, abrasions, or severe dermatitis are relative contraindications to any access routes. Furthermore, use of any access technique with which an unsupervised clinician is inexperienced is contraindicated. Other relative contraindications include those conditions predisposing to sclerosis or thrombosis of the central veins, such as vasculitis, prior long-term cannulation, or illicit IV drug use via any of the deep venous systems.

**Subclavian Approach**

Patients in whom subclavian access is contraindicated include those who have undergone previous surgery or trauma

\* Note that these contraindications are generally relative and clinical use of this technique must be based on clinical conditions and available options for vascular access.

May use contralateral side.

May use ipsilateral side.

§ May use standard (short) large-bore IV catheters.

involving the clavicle, the first rib, or the subclavian vessels; patients who have undergone previous radiation therapy to the clavicular area; patients with significant chest wall deformities; and those with marked cachexia or obesity. However, physicians in burn centers routinely place central catheters through burned areas. Patients with

unilateral deformities not associated with pneumothorax (e.g., fracture clavicle) should be catheterized on the opposite side.

Subclavian venipuncture is not contraindicated in patients who have penetrating thoracic wounds unless the injuries involve the superior vena cava. Generally, the vein on the same side of the chest wound should be cannulated to avoid the possibility of bilateral pneumothoraces, unless one suspects that the subclavian vessels have been injured. In such instances, the opposite side is cannulated. [41] In penetrating wounds that may involve the superior vena cava, neither subclavian vessel should be cannulated, and venous access below the diaphragm should be sought. Use of the subclavian approach in patients with coagulation disorders or in those receiving heparin therapy is contraindicated. A more visible and accessible site should be chosen (preferably percutaneous cannulation of a peripheral vein), because it is impossible to apply direct pressure to an oozing subclavian vein. The procedure should not be performed in combative patients because of the greater possibility of pneumothorax, vessel laceration, air embolism, and septic complications. Although subclavian venipuncture has been used successfully in children <2 years of age, [42] it is not generally recommended for use in small children. [43]

**Internal Jugular Approach**

Cervical trauma with swelling or anatomic distortion at the intended site of IJ venipuncture is the most important contraindication to the IJ approach. Neck motion is limited when the IJ central line is in place, and this limitation represents a relative contraindication in conscious patients. Although bleeding disorders are relative contraindications to central venous cannulation, the IJ approach is preferred over the subclavian route, as the IJ site is compressible. In the setting of severe bleeding diatheses, the femoral approach should be considered. Carotid arterial disease (obstruction or atherosclerotic plaques) is a relative contraindication to IJ cannulation, since inadvertent puncture or manipulation of the artery may dislodge a plaque. In addition, prolonged compression of the artery to control bleeding may impair cerebral circulation if collateral blood flow is compromised. If a preceding subclavian catheterization has been unsuccessful, the ipsilateral IJ route is generally preferred for a subsequent attempt. In this manner, bilateral iatrogenic complications are avoided.

**External Jugular Approach**

The greatest disadvantage of the EJ approach for central venous access is the time required to successfully pass a J wire and catheter into appropriate position. [44] However, the ease and relative safety of this approach make the EJ vein an excellent site of simple IV cannulation for fluid or drug administration or blood sampling.

**Femoral Vein Approach**

Contraindications to femoral cannulation include trauma to the groin, iliac vessels, or inferior vena cava. Percutaneous femoral line placement is not recommended in a

patient who

is in cardiac arrest or has an absent femoral pulse, unless other alternatives have been exhausted. [45] In a canine model of cardiac arrest, palpable pulsations in the groin were found to be venous rather than arterial in origin 50% of the time. [46]

## ANATOMY

### Subclavian System

The subclavian vein begins as a continuation of the axillary vein at the outer edge of the first rib (Fig. 24-1) (Figure Not Available) . It joins the IJ vein to become the innominate vein 3 to 4 cm proximally. The subclavian has a diameter of 10 to 20 mm and is valveless. After crossing the first rib, the vein lies posterior to the medial third of the clavicle. It is only in this area that there is an intimate association between the clavicle and the subclavian vein. The costoclavicular ligament lies anterior and inferior to the subclavian vein, and the fascia contiguous to this ligament invests the vessel. Posterior to the vein, separating it from the subclavian artery, lies the anterior scalene muscle, which has a thickness of 10 to 15 mm. The phrenic nerve passes over the anterior surface of the scalene muscle and runs immediately behind the junction of the subclavian and IJ jugular veins. The thoracic duct (on the left) and the lymphatic duct (on the right) pass over the anterior scalene muscle and enter the subclavian vein near its junction with the IJ vein. Superior and posterior to the subclavian artery lies the brachial plexus. The dome of the left lung may extend above the first rib, but the right lung rarely extends this high.

### Jugular System

The anatomy of the IJ vein is relatively constant, regardless of body habitus. The vein drains the cranium, beginning as the superior jugular bulb, which is separated from the floor of the middle ear by a delicate bony plate. The IJ vein emerges deep to the posterior belly of the digastric muscle. At its origin the IJ vein courses adjacent to the spinal accessory, vagus, and hypoglossal nerves, as well as the internal carotid artery. Several tributary veins enter the IJ vein at the level of the hyoid bone. The IJ vein, the internal (and, later, the common) carotid artery, and the vagus nerve course

**Figure 24-1** (Figure Not Available) *A* and *B,* Subclavian vein and local anatomy. *C,* Subclavian area, sagittal section. *( A from Linos D, Mucha P, von Heerden J: The subclavian vein: A golden route. Mayo Clin Proc 55:316, 1980. B from Davidson JJ, Ben-Hur N, Nathan H: Subclavian venipuncture. Lancet 2:1140, 1963. C from Brahos G: Central venous catheterization: SC approach. J Trauma 17:873, 1977. Reproduced by permission.)*

together in the carotid sheath. The IJ vein occupies the anterior lateral position in the carotid sheath. [47] The only structure that maintains a fixed anatomic relationship with the IJ vein is the carotid artery. The vein invariably lies lateral and slightly anterior to the carotid artery, and the course of the artery serves as a guide to venous cannulation. At the level of the thyroid cartilage, the IJ vein can be found just deep to the

sternocleidomastoid muscle (Fig. 24-2) (Figure Not Available) .

The IJ vein emerges from under the apex of the triangle of the 2 heads of the sternocleidomastoid muscle and joins the subclavian vein behind the clavicle. As the vein approaches its supraclavicular junction with the subclavian vein, it assumes a more medial position in the triangle formed by the 2 heads of the sternocleidomastoid muscles, following the anterior border of the lateral head. In this lower cervical region, the common carotid artery assumes a deep paratracheal location. The brachial plexus is separated from the IJ vein by the scalenus anterior muscle. The phrenic nerve is anterior to the scalenus anterior muscle. Although quite deep, the stellate ganglion lies anterior to the lower brachial plexus.

Unlike the subclavian vein, the IJ vein is quite distensible. The vessel diameter is increased with performance of a Valsalva maneuver and the assumption of the head-down (Trendelenburg) tilt position. Prolonged palpation of the carotid pulse will decrease the diameter of the IJ vein. [47] Rotating the head 90° toward the opposite side or extending the neck will not change the size of the IJ vessel significantly. Severe rotation of the head, however, will bring the sternocleidomastoid muscle anterior or medial to the IJ vein. Severe rotation may make it impossible to cannulate the IJ vein without first traversing the carotid artery when the anterior approach is used. The diameter of the IJ vessel is largest below the cricoid ring, where it may reach 2 to 2.5 cm. [47]

**Figure 24-2** (Figure Not Available) Structures in a dissection of the neck. The superficial veins and the sternocleidomastoid muscle have been removed, as have the submandibular gland and a segment of the facial vein. The cutaneous nerves have been cut down to short stumps arising from the second, third, and fourth cervical nerves. The internal jugular vein is drawn somewhat more medial in this illustration than is commonly found. *(From Hollinshead WH: Textbook of Anatomy. 3rd ed. New York, Harper & Row, 1974, p 765. **Femoral System**

The femoral vein is most easily cannulated percutaneously in patients with a palpable femoral pulse. The femoral vein lies just medial to the artery in the femoral canal below the inguinal ligament. Beneath the femoral vessels lie the psoas muscle and the hip (Fig. 24-3) (Figure Not Available) .

**Basilic and Cephalic System**

Considerable variation is present in the venous vasculature of the upper extremities. Nonetheless, the cephalic and basilic veins can usually be located in the volar antecubital region (Fig. 24-4) (Figure Not Available) . The interconnecting median antecubital vein is often the most prominent, thus making it a popular site for venipuncture during blood sampling. The basilic vein merges proximally with the brachial vein to form the axillary vein, which subsequently meets the cephalic vein to form the subclavian vein near the distal clavicle. The IJ and EJ veins join the subclavian vein to form the innominate vein bilaterally. Many venous valves exist in the peripheral vessels. Vascular anastomoses may permit aberrant advancement of a long line from the upper extremity. In particular, lines threaded up the cephalic vein may dead-end in a

venous plexus or enter the EJ vein. Furthermore, lines passed through the basilic vein may easily enter the IJ vein.

## EQUIPMENT

The materials required for central venous cannulation are listed in Table 24-3 . The catheter may be of the over-the-needle or through-the-needle variety, or it may be a component in a guide wire system that combines both technologies (see Chapters 20 and 21) .

**Figure 24-3** (Figure Not Available) The right femoral vessels and some of their branches. The femoral nerve (not shown) lies lateral to the artery and may be deep to the artery. *(From Warwick R, Williams PL [eds]: Gray's Anatomy. 35th ed. Edinburgh, Churchill Livingstone, 1973, p 676. *Over-the-needle devices* (such as the Angiocath) use a tapered plastic catheter that passes through the vessel wall into the lumen using the needle tip as a guide (Fig. 24-5) . There are several advantages of this system. The catheter does not pass through a sharp needle, and the risk of shearing with resultant catheter embolization is thus decreased. The needle is removed following cannulation, making a guard unnecessary. The hole made by the needle in the vessel wall is smaller than the catheter, producing a tighter seal. Because these devices are placed via a percutaneous stick without the use of the guide wire technique, these catheters are used primarily when rapid central venous access is required (e.g., during a cardiac arrest). The catheters are not suitable for high-volume fluid resuscitation, and they are too small for passage of a pacemaker lead.

The main disadvantage of the over-the-needle system is the relatively short length of the catheter. Also, catheter threading is made more difficult by the longer length of the

**Figure 24-5** Most central venous catheterization uses the Seldinger technique, but for rapid access to the central venous system, the over-the-needle catheter/syringe system is ideal. The upper catheter is a 16-ga 5¼-in. Angiocath (shown assembled and attached to syringe and also shown disassembled) that can access the subclavian, internal jugular, and femoral vein in an adult. The lower 18-ga 1¼-in. Jelco catheter can be attached to a syringe to cannulate the central veins in an infant. The operator should advance the needle very slowly and aspirate continually. The flashback into the hub may be delayed, causing the needle to traverse the vein before the operator realizes that the lumen has been entered.

needle relative to the catheter. With over-the-needle catheters, the needle extends a few millimeters past the tip of the catheter. A blood return will be obtained when the tip of the needle is in the vein, but the catheter may actually be outside the lumen. If the needle is withdrawn before the catheter is advanced, the catheter tip will remain outside the vein. One must be certain to keep the needle steady and advance the catheter forward over the needle to ensure intravascular placement.

*Through-the-needle devices* (such as the Intracath) use a catheter of smaller gauge than the puncturing needle. Generally, the needle is 14 ga, and the catheter is 16 ga. This catheter is threaded through the lumen of the needle after the vessel is entered by the needle tip. After threading, the needle is withdrawn and left on the skin surface with a plastic guard protecting the patient and the catheter. A modification of this system uses a detachable hub on the catheter so that the needle can be removed. The main advantage of through-the-needle systems is that catheters of any length may be used. Also, the rate of successful entry of the catheter into the vessel lumen may be higher.

The main disadvantage of the through-the-needle system is the potential for catheter shearing during or after insertion. Systems using a detachable catheter hub (Deseret 755) allow the needle to be removed completely following insertion but require assembly of small plastic parts. This is undesirable in an emergency situation. Another disadvantage of through-the-needle devices is that the caliber of the catheter must be smaller than that of the needle. Standard catheters are 16 ga, a size that is not optimal for rapid infusion of resuscitation fluids or blood.

Newer types of catheters tend to combine through-the-needle and over-the-needle technology. The Argyle Intramedicut catheter has a short over-the-needle catheter that

serves

as an introducer for a longer (30 cm) infusion catheter. Following successful cannulation of the vein with the introducing catheter, the needle is withdrawn, and the infusion catheter is advanced through the introducing catheter.

Probably the most commonly used means of central venous cannulation today is the Seldinger (guide wire) technique, by which a thin-walled needle is used to introduce a guide wire into the vessel lumen (see Chapter 21) . A larger infusion catheter is then advanced over the wire into the vein. Physicians inexperienced with guide wire systems may encounter difficulty passing the guide wire. At times detachment of the syringe from the thin-walled needle may lead to loss of the needle's intravascular position. The need to detach the syringe can be eliminated by use of the Arrow Safety Syringe. This device incorporates a hollow syringe through which the guide wire can be passed directly into the thin-walled needle without detachment. In addition, this reduces the risk of air embolism, which can occur when the needle is open to the air.

There is no evidence that the complications of subclavian cannulation are related to the size of the puncturing needle. Schug and colleagues compared subclavian venipuncture performed with a standard through-the-needle device (Deseret Intracath 3162) to a system using a thin-walled needle and guide wire (Arrow AK 04300). They found no difference in the success or complication rates, but there was a significantly higher incidence of catheter misplacement or malfunction when the guide wire technique was used. [48]

Although more steps are required with the guide wire technique, it has several uses once it is mastered. Minor modification of the process and the equipment used permits the insertion not only of standard infusion catheters, but also of multilumen catheters, large-bore rapid infusion systems, and introducer devices. If this degree of flexibility is desired, use of Seldinger-type systems may be advantageous, despite their significantly greater cost.

Catheter length and size are also important considerations. The superior vena cava begins at the level of the manubriosternal junction and terminates in the right atrium, approximately 5 cm lower. For lines placed in the subclavian, jugular, basilic, and cephalic systems, the proper position of the catheter is in the superior vena cava, *not the right atrium or ventricle*. Therefore, the catheter should be threaded approximately 2 cm below the manubriosternal junction. One can estimate this distance by placing the catheter parallel to the chest wall before insertion. The standard catheters marketed for subclavian venipuncture are 20 to 30 cm long. The 30-cm catheters should not be inserted fully into the subclavian vein, because the catheter tip is likely to terminate in the right atrium or ventricle. Generally, 20 cm is an appropriate length for the average adult male, but one should consider advancing the catheter less than its full length in small adults. Proper placement is best confirmed by a postprocedure chest radiograph, not by preplacement measurements.

Central veins are often cannulated in seriously ill patients who will require subsequent pulmonary artery wedge pressure monitoring or transvenous pacemakers. Any CVP

catheter that is initially inserted should have a lumen that is large enough to accept a guide wire, should one need to later insert an introducer device for placement of the aforementioned devices. Not all commercially available CVP catheters will accept a guide wire through the lumen.

A number of different catheters are currently manufactured. It is best to use one brand routinely and to ensure that all medical personnel are thoroughly schooled in its use. Stocking several different catheter types adds unnecessary confusion to the duties of supply clerks and nurses, not to mention the physician who might be handed an unfamiliar brand during a patient resuscitation.

## VENIPUNCTURE TECHNIQUE

Strict adherence to the principles of sterile technique is important if septic complications are to be avoided. Violation of these principles for the sake of speed is seldom justified. The few extra seconds required to put on gloves and to swab and drape the chest will rarely make a critical difference in patient survival. It is recognized that optimum practice of aseptic technique often cannot take place during a resuscitation. For this reason, all central lines placed in this setting should be replaced at the earliest possible opportunity.

The area of the needle puncture should be widely prepared with povidone-iodine solution. In iodine-allergic patients, pHisoHex or Hibiclens are acceptable alternatives. If subclavian or IJ approaches are planned, the prepared area should include puncture sites for the IC and SC subclavian and IJ approaches. This permits the physician to change the site following an unsuccessful attempt without repeating the preparation. In this circumstance, a standard preparation should include the ipsilateral anterior neck, the supraclavicular fossa, and the anterior chest 3 to 5 cm past the midline and the same distance above the nipple line. Preparation for femoral access includes shaving the groin as needed, followed by application of povidone-iodine solution to cover an area the breadth of, and extending 10 cm above and below, the inguinal ligament.

Levy and associates described the virtual elimination of catheter contamination by inserting the catheter through a previously placed iodophor-impregnated sterile film after the usual sterile preparation and draping. [49] However, Clayton and colleagues found no statistical difference in catheter contamination rates during 137 insertions using an aseptic technique versus a "standard nonsterile" technique of insertion. [50] The patients and their skin were prepared similarly in both groups, except for the presence or absence of sterile towels for draping. Physicians in the aseptic group prepared as for surgery, with a 5-minute scrub and full gown, hat, mask, and gloves, whereas the "nonsterile" physicians did not necessarily even wash their hands or use sterile gloves. The contaminating organism in 87.1% of the overall cases was *Staphylococcus epidermidis.*

The need to perform an operating suite-style preparation in patients receiving hyperalimentation is unproved. In a study of 63 patients with long-term subclavian catheterization for hyperalimentation, Merk and Rush reported only 1 infection using a simple iodophor spray preparation. They emphasized that experienced personnel have

prime importance in the prevention of infection. [24]

Each of the approaches to central venous cannulation is described separately below. It is assumed that proper sterile procedure and any needed local anesthesia will be provided. As in any invasive task, the procedure should be described briefly to awake patients, and each step should be restated as it is about to be performed. After the following descriptions of the common approaches to the central veins, discussion

of catheter passage using the 3 catheter systems, puncture site care, placement verification, and other adjuncts to the procedure will be summarized.

**Subclavian Vein, IC Approach**

Descriptions of subclavian venipuncture often unduly focus on angles and landmarks and overstate the effects of patient positioning. The most important factors governing success or failure are knowledge of anatomy and meticulous attention to the details of the procedure. [51]

**Positioning.**

The patient is placed in the supine position with the head in a neutral position and the arm abducted. Placing the patient in the Trendelenburg position (10° to 15°) decreases the risk of air embolism. The claim that this position distends the vein is controversial at best. [52] Land has demonstrated by venographic studies that there is no change in the diameter of the subclavian vein associated with the Trendelenburg position. [53] Because his patients were normovolemic, this finding cannot necessarily be extrapolated to hypovolemic patients. Nonetheless, the vessel is hemmed by the semirigid costoclavicular ligament on its anteroinferior aspect and therefore will not distend in a direction that facilitates IC venipuncture. [11] Magnetic resonance imaging clearly demonstrates that the caliber of the subclavian vein is determined by its attachment to adjacent structures and is not affected by the CVP. [54] These findings are in conflict with those of Fortune and colleagues, who noted mild dilation of the subclavian vein on B-mode ultrasound of normal subjects during Trendelenburg positioning. [55]

Abduction of the arm has been recommended to flatten the deltoid bulge. [56] This is sometimes a helpful maneuver in muscular individuals but is not generally necessary. Land has demonstrated that abduction moves medially the point at which the subclavian vein passes beneath the clavicle. [53] Turning the head to the opposite side, as advocated by Borja, [57] has no effect on the vessel size or on the relative positions of the vessel and the clavicle. [53] This maneuver does change the relative positions of the subclavian and IJ vein and has been postulated to cause an increased incidence of catheter malposition in the jugular vein. [54] Placing a pillow under the back is commonly recommended to make the clavicle more prominent, but as the shoulder falls backward, the space between the clavicle and first rib narrows, making the subclavian vein less accessible. [56] Jesseph and colleagues demonstrated significant compression of the subclavian vessels between these bony structures as the shoulders retract. [54]

**Venipuncture site.**

The right subclavian vein is usually cannulated because of the lower pleural dome on the right and because of the need to avoid the left-sided thoracic duct. The anatomically more direct route between the left subclavian vein and the superior vena cava is a theoretic advantage of left-sided over right-sided subclavian venipuncture. It has not been proved that there is a higher incidence of catheter malposition when the right IC approach is used.

In the conscious patient, the point of needle entry is anesthetized with 1% lidocaine. SQ infiltration of the periosteum of the clavicle will make the procedure less painful but is not always necessary. When using a through-the-needle device, one attaches the 14-ga needle to a 10-mL non-Luer-Lok syringe. When using the Deseret Intracath 3162 system, it is advisable to remove the catheter from the plastic package to facilitate later passage through the needle (Fig. 24-6) (Figure Not Available) .

Opinions vary as to the best point of needle entry. The

**Figure 24-6** (Figure Not Available) *A,* Insertion of a through-the-needle device, as packaged. *B,* It is advisable to remove the packaged catheter and to puncture the vein with a syringe attached to the needle, then carefully remove the syringe and pass the catheter through the needle. Contrary to the illustration, latex gloves should be worn. *(Redrawn from Gallitano AL, Kondi ES, Deckers PJ: A safe approach to the subclavian vein. Surg Gynecol Obstet 135:97, 1972. Reproduced by permission.)*

junction of the middle and medial thirds of the clavicle is the standard site. There the vein lies just posterior to the clavicle and just above the first rib, which acts as a barrier to penetration of the pleura. This protective effect is lost when a more lateral location is chosen. Westreich advocates entry just laterally and inferiorly to the junction of the clavicle and the first rib, with the needle aiming at this junction. [58] Simon advocates entry at the site of a small tubercle in the medial aspect of the deltopectoral groove. [59] In our opinion, the point of entry is less important than the direction taken by the needle after entry. Points lateral to the midclavicle should be avoided, because this location requires a deeper puncture and potentially increases the risk of pneumothorax.

**Needle orientation.**

The *needle bevel should be oriented inferomedially* for the IC approach to direct the catheter toward the innominate vein rather than toward the opposite vessel wall or up the IJ vein (Fig. 24-7) . Alignment of the needle bevel with markings on the barrel of the syringe permits awareness of bevel orientation after skin puncture. Some investigators advise puncturing the skin with a No. 11 scalpel blade to avoid skin plugs in the needle. Others suggest filling the syringe with 2 to 3 mL of local anesthetic to both anesthetize the SQ tissue and flush the needle.

Before insertion of the needle, the left index finger is placed in the suprasternal notch and the thumb is positioned at the costoclavicular junction (Fig. 24-8) (Figure Not Available) . These serve as reference points for the direction of needle travel. The

needle is aimed immediately above and posteriorly to the index finger. Vessel entry, signaled by a flashback of dark venous blood, usually occurs at a depth of 3 to 4 cm. If the needle

tip is truly intraluminal, there will be free flow of blood. The return of pulsatile flow signifies arterial puncture. A single arterial puncture without laceration rarely causes serious harm. Use of this technique eliminates the need to measure angles, to "walk" the clavicle, or to concentrate excessively on maintaining the needle parallel to the chest wall. All of these techniques are based on fear of complications rather than knowledge of anatomy. [57] Mogil and colleagues have advocated changing the direction of the needle after it passes posteriorly to the lower edge of the clavicle. [9] In our opinion,

this adds a step that is not only unnecessary but also dangerous. One should avoid any sweeping motions of the needle tip to prevent unseen injuries. In patients who are being ventilated with positive pressure, it is advisable to halt ventilation for a moment as the needle penetrates the chest wall. Interruptions should be kept to a minimum and should not exceed the 30-second standard. [60]

**Unsuccessful attempts.**

Cannulation of the subclavian vein may not be successful on the first attempt. It is reasonable to try again, but after 3 or 4 unsuccessful attempts, it is best to try another approach or allow a colleague to attempt the procedure. One must use a new setup each time blood is obtained, because clots and tissue will clog the needle and mislead the physician even if subsequent procedures are performed correctly. If several attempts are made, the admitting physician or anesthesiologist must be informed so that proper precautions are taken to identify subsequent complications. It is advisable to obtain radiographs of the chest even after unsuccessful attempts. If the initial puncture site was properly placed, then for aesthetic reasons, one should use the same needle hole for subsequent attempts (i.e., one should avoid an embarrassing pincushion appearance of the upper chest). If the subclavian route is unsuccessful on one side, it is best to attempt an IJ catheterization on the same side rather than attempt a subclavian cannulation on the opposite side. In this manner, bilateral complications are avoided.

**Subclavian Vein, SC Approach**

**Positioning.**

The goal of the SC technique is to puncture the subclavian vein in its superior aspect just as it joins the IJ vein. The needle is inserted above and behind the clavicle, lateral to the sternocleidomastoid muscle. It advances in an avascular plane, away from the subclavian artery and the dome of the pleura. The right side is preferred because of the lower pleural dome, because it is the direct route to the

superior vena cava, and because the thoracic duct is on the left side. The Trendelenburg position may be helpful for distending the vein, because the subclavian vein is not bound by fasciae on its superior aspect. [27] The patient's head may be turned to the opposite side to help identify the landmarks.

**Needle orientation.**

After the area of the supraclavicular fossa has been prepared and draped, a point is identified 1 cm lateral to the clavicular head of the sternocleidomastoid and 1 cm posterior to the clavicle (Fig. 24-9) . The area is anesthetized with 1% lidocaine. If a 3-cm-long needle is used for anesthesia, it may also be used to locate the vessel in a relatively atraumatic manner. The subclavian vein can almost always be located with this needle because of the vein's superficial location and the absence of bony structures in the path of the needle. A 14-ga needle (or 18-ga thin-walled needle) is then advanced, following the path of the scout needle; gentle negative pressure is applied using an attached syringe.

When seeking the subclavian vein, the needle is aimed so as to bisect the clavicosternomastoid angle, with the tip

**Figure 24-9** *A* and *B,* For the supraclavicular approach, the needle is inserted above and behind the clavicle, bisecting the angle made by the clavicle and the lateral border of the sternocleidomastoid muscle (clavisternomastoid angle). The point of entry is 1 cm lateral to the clavicular head of the muscle and 1 cm posterior to the clavicle. The needle traverses an avascular plane, puncturing the junction of the subclavian and internal jugular vein behind the sternoclavicular joint. The right side is preferred because of a direct route to the superior vena cava and the absence of the thoracic duct. The needle is directed 45° from the sagittal plane and 10° to 15° upward from the horizontal plane, aiming toward the contralateral nipple. Note that the vein is just posterior to the clavicle at this juncture. *C,* Sagittal view of the supraclavicular area. As the subclavian vein passes over (and somewhat anterior to) the first rib, it is separated from the subclavian artery by the anterior scalene muscle. The dome of the pleura is posterolateral to the confluence of the great veins.

pointing just caudal to the contralateral nipple. The *bevel is oriented medially* to prevent catheter trapping against the inferior vessel wall. The tip of the needle is pointed 10° above the horizontal. Successful vessel puncture generally occurs at a depth of 2 to 3 cm.

### IJ Approach

**Positioning.**

In preparation for all 3 IJ approaches, the patient is tilted 15° to 30° in the Trendelenburg position and the head is turned slightly away from the side of venipuncture. The IJ vein is distensible, and tilting the patient increases the diameter of the vessel. If the patient is awake, he or she should be instructed to perform a Valsalva maneuver during vessel cannulation. In the unconscious patient, abdominal compression by an assistant can be used to help distend the vein.

**Venipuncture site.**

Familiarity with the anatomy of the neck is important to increase the probability of successful cannulation and to avoid complications. Most authors favor cannulation of the right side of the neck, which provides a more direct route to the superior vena cava and avoids the thoracic duct. Although it is probably clinically insignificant, the cupola of the pleura is also slightly lower on the right side. The left IJ approach is more circuitous and, when used with a stiff Teflon catheter, may result in a major venous puncture leading to hydrothorax, hydromediastinum, or even pericardial tamponade. [61] [62] [63] [64]

**Central route.**

This approach is favored by Kaplan and Miller, who believe that the incidence of cannulation of the carotid artery is decreased and the cupola of the lung is avoided with this method. [65] The triangle formed by the clavicle and the sternal and clavicular heads of the sternocleidomastoid is first palpated and identified. The lateral border of the carotid pulse can be marked by a local anesthetic skin wheal or a marking pen, and all subsequent needle puncture can be performed laterally to that point.

Some practitioners prefer to attempt cannulation with the catheter apparatus initially. Others use a small-gauge "locator" needle to locate the vein. The smaller needle allows one to ascertain the location of the vein and minimizes injury to deep structures by an incorrectly placed larger needle. Use of a locator needle can be time consuming in a cardiac arrest situation.

When using the scout needle technique, a 22-ga, 3 cm needle attached to a 5- to 10-mL syringe is introduced near the apex of the triangle and is directed caudally at an angle 30° to 40° to the skin. The needle should initially be directed parallel and slightly laterally to the course of the carotid artery (Fig. 24-10) (Figure Not Available) . If 3 fingers are lightly placed over the course of the carotid artery, the parallel course of the IJ vein can be estimated. The vein consistently lies just lateral to the carotid artery. Prolonged deep palpation of the carotid artery may decrease the size of the vein, and the 3-finger technique should be used only long enough to identify the course of the artery.

Negative pressure should be maintained on the syringe at all times as the needle is

advanced or retracted. The vein is more superficial than might be expected, and deep probing with the needle should be avoided; the vein is usually encountered at a depth of 1 to 1.5 cm. If the IJ vein is not entered at a depth of 3 to 5 cm, the needle should be withdrawn to just below the skin surface and directed toward the ipsilateral nipple underneath the medial border of the

lateral (clavicular) head of the sternocleidomastoid. *During any type of central venous cannulation, a needle must always be withdrawn to the surface before being redirected to avoid lacerating or otherwise damaging important nerves, vessels, or other structures*.

The vein should be entered at 1 to 3 cm, and dark blood should be easily aspirated (bright red blood indicates carotid artery penetration and the need for needle repositioning). The locator needle is withdrawn and replaced with a 14-ga, 5-cm needle attached to a syringe. A drop of blood from the locator needle can be placed at the edge of the sterile field in line with the point of vessel entry, thus serving as a guide to recannulation. The larger needle is advanced through the skin along the path determined by the smaller needle until blood is aspirated. Care must be taken to cover the needle hub with a gloved thumb whenever the needle lumen is exposed to air. This practice will prevent an air embolus when the patient inspires.

The central approach has been used in children with good success. [36] [66] However, success is greater with larger infants (>10 kg) and those with higher CVPs (>10 cm $H_2O$). With infants and children, needle puncture occurs at the apex of the triangle bordered by the 2 heads of the sternocleidomastoid muscle and the clavicle. Similar to the approach for adults, one passes a 22-ga needle attached to a 2- to 5-mL non-Luer-Lok syringe into the skin at a 45° angle and directs it caudally and laterally toward the ipsilateral nipple. The vessel is usually entered at a depth of 1 to 2 cm. The locator needle is then withdrawn, and a 17- to 19-ga needle is inserted into the skin until the IJ vein is penetrated.

**Posterior and anterior routes.**

For the *posterior approach*, the skin is entered at the lateral edge of the sternocleidomastoid muscle one third of the way from the clavicle to the mastoid process (Fig. 24-11) (Figure Not Available) . The locator needle is directed caudally and medially toward the sternal notch until blood is aspirated.

To perform the *anterior approach* described by Mostert

and coworkers, the course of the carotid is identified and marked by the index and middle fingers (Fig. 24-12) (Figure Not Available) . [67] The small needle should then enter the skin at the midpoint of the medial aspect of the sternocleidomastoid muscle. The needle is directed at an angle of 30° to 45° to the coronal plane caudally toward the ipsilateral nipple. Kaplan and Miller [65] alter this approach by starting at the level of the thyroid notch. The proximity of the carotid artery in the anterior approach may prohibit venous cannulation without

**Figure 24-12** (Figure Not Available) Anterior approach to the internal jugular vein. The index and middle fingers are outlining the course of the carotid artery. Contrary to the illustration, surgical gloves should be worn during the procedure. *(From Delfaque RJ: Percutaneous catheterization of the internal jugular vein. Anesth Analg 53:116, 1974. Reproduced by permission.)*

carotid puncture. [47] Legler and Nugent report the use of Doppler ultrasound to facilitate difficult IJ cannulation, a matter discussed in more detail below. [68] Use of ultrasound guidance is obviously restricted to nonemergency situations.

**EJ Vein Approach**

**Positioning.**

With the patient in the Trendelenburg position, the EJ vein is distended by instructing the patient to perform a Valsalva maneuver and then tamponading the vein just cephalad to the clavicle with a finger.

**Venipuncture.**

The vein is approached from the side while slight traction is placed on the vein to stabilize it. The needle is advanced at a small angle from the skin plane (about 10°) until the operator feels it "pop" into the lumen of the vein. The needle or catheter should be advanced slightly after feeling the pop to ensure intraluminal placement. As discussed below, use of the EJ vein as a site for central vein access requires the use of a guide wire.

**Femoral Vein Approach**

**Positioning and needle orientation.**

The patient must be supine. The femoral pulse is identified and the scout needle (at least 4.4 cm length) is inserted at 45° to the skin in a cephalic direction just medial to the femoral pulsation. Because CPR can produce venous pulsations, unsuccessful venous aspiration medial to the pulsations should be followed by an attempt directly over the pulsations.

During needle advancement, negative pressure is maintained within the syringe at all times while the needle is under the skin. The needle is directed posteriorly and advanced until the vein is entered, as identified by a flash of dark, nonpulsating blood. If the vessel is penetrated when the syringe is not being aspirated, the blood flash may be seen only as the needle is being withdrawn.

**Basilic and Cephalic Approach**

**Venipuncture.**

The basilic and cephalic venous systems are entered through the large veins in the antecubital fossa (Fig. 24-13) (Figure Not Available) . Tourniquet placement aids venous distention

**Figure 24-13** (Figure Not Available) Proximal anatomy of the basilic-cephalic venous system. *(From Webre DR, Arens JF: Use of the cephalic and basilic veins for introduction of central venous catheters. Anesthesiology 33:389, 1973. Reproduced by permission.)*

and initial venous puncture. When veins are not visible, they may be reached with a cutdown procedure, as described in Chapter 22 . The basilic vein, located on the medial aspect of the antecubital fossa, is generally larger than the radially located cephalic vein. Furthermore, the basilic vein generally provides a more direct route for passage into the axillary subclavian vein and superior vena cava.

## CATHETER PASSAGE TECHNIQUE

Once a venous flashback into the syringe is obtained, the syringe is detached from the needle, and a catheter is passed. Removing the syringe may be frustrating if the needle tip is dislodged from the lumen of the vein (Fig. 24-14) (Figure Not Available) . If the syringe is tightly attached to the needle, a hemostat may be used to grasp and secure the needle hub during removal of the syringe. Needle tip displacement may also occur if blood specimens are drawn at this time. Hence, it is best to delay blood sampling until the catheter has been advanced. The needle hub should be occluded with the thumb to avoid air embolism.

The technique used for catheter passage is dependent on the site of venipuncture and the needle-catheter system used. Many variations are available, but the most common

**Figure 24-14** (Figure Not Available) Subclavian venipuncture, venous backflow. After venipuncture, the syringe is removed carefully to avoid inadvertent motion of the needle tip, which may dislodge the needle from the vein lumen. A hemostat may help hold the needle hub to prevent motion during withdrawal of the syringe. *(From Phillips SJ: Technique of percutaneous subclavian vein catheterization. Surg Gynecol Obstet 127:1080, 1968. Reproduced by permission.)*

**Figure 24-15** (Figure Not Available) Internal jugular line secured by looping around the ear. *(From*

method uses the guide wire technique, described further in Chapter 21 . If a through-the-needle catheter is used, it should be emphasized that *at no time should a catheter be withdrawn through the needle or forced when it will not thread into the vessel easily*. A properly placed catheter should thread easily. Difficulty in catheter threading may be caused by passage out of the vessel lumen, trapping against the opposite vessel wall, kinking, or deviation up the IJ vein. *When the catheter will not thread, the needle and catheter should be withdrawn as a unit*; the vein should then be recannulated before reattempting catheter passage. Proper direction of the needle bevel will help alleviate catheter trapping.

Once the catheter has been passed, it is secured to the patient. All tubing and connections should first be checked for tightness to prevent air embolism, fluid loss, or bleeding. The technique for securing a catheter depends on the type of equipment and the site of puncture. In general, all catheters should be secured with sutures (or skin staples [69] ) and a sterile dressing placed. Most systems have some type of needle guard and/or anchoring device to simplify securing of the catheter. Since dressings are inspected and changed periodically, it is prudent to place a simple dressing, avoiding excessive amounts of gauze and tape. An effective method for securing an IJ catheter is shown in Figure 24-15 (Figure Not Available) . Care is taken to protect the skin against maceration if a plastic needle guard is used. Transparent dressings such as Op-Site are popular simple dressings.

**EJ Vein Approach**

Use of the EJ vein for achieving central venous access requires use of a guide wire. After cannulation of the vein and intraluminal placement of the guide wire, the guide wire is advanced into the thorax by rotating, teasing, or otherwise manipulating the tip into the central venous circulation (Fig. 24-16) (Figure Not Available) . Guide wire advancement is the most difficult and time-consuming portion of the procedure, and this time constraint limits the usefulness of the technique in an emergency. A small-radius J-tipped wire, a distended vessel lumen,

**Figure 24-16** (Figure Not Available) Insertion of a catheter over a wire via the external jugular vein. Successful passage may require many attempts and manipulations of the J-wire to navigate turns and valves. *(From Blitt CD, Wright WA, Petty WC: Central venous catheterization via the external jugular vein, a technique employing the J-wire. JAMA 229:817, 1974. Reproduced by permission.)*

and exaggeration of patient head tilt, coupled with skin traction, may facilitate successful guide wire passage. Partially withdrawing the wire and twisting it 180° before readvancing the tip may also be helpful.

Once the wire is in the correct position, a standard central venous catheter may be threaded over the wire, or a sheath introducer may be passed (with the aid of a vein dilator, as described in Chapter 21) to facilitate the introduction of a transvenous pacemaker or a pulmonary artery catheter. Even with central venous placement of the guide wire, the catheter may not pass centrally. After catheter placement, the guide wire

is removed, and the IV line is attached.

Central venous catheterization via the EJ vein is time consuming and often difficult. It also sometimes results in significant complications, especially with the use of the left EJ vein. [36] [62] For these reasons, it is not recommended in an emergency. Nonetheless, the EJ approach does provide central venous access in selected stable patients. Furthermore, simple cannulation with a short catheter is useful for fluid and drug administration during an emergency when peripheral veins cannot be cannulated.

**Femoral Vein Approach**

Once in the femoral vein, the needle is stabilized; often, a hemostat is helpful for holding the needle during removal of the syringe. A premeasured section of a 90-cm catheter may then be inserted using a through-the-needle system. One determines the appropriate length by holding the catheter over the patient's body and estimating the distance from the skin puncture site to the right atrium. Contamination of the catheter must be avoided while this maneuver is performed. Once the catheter is placed, it is secured with sutures and is dressed in the same manner as other central lines.

In situations requiring rapid volume infusion, in the absence of intra-abdominal trauma, the femoral vein may be cannulated with a sheath introduced via the guide wire technique. The introducer will allow rapid transfusion of large volumes of blood or crystalloid solution for fluid resuscitation. [33] Various catheters are available with single large-bore lumens or as many as 3 lumens for infusion of separate IV solutions and medications. The femoral vessels may also be cannulated under direct visualization using a cutdown technique (see Chapter 22) .

**Basilic and Cephalic Approach**

Once a vein has been entered, a premeasured length of a 90-cm catheter is threaded aseptically into the superior vena cava. Catheter length is estimated using the combined distance from the puncture site to the axilla and from the axilla to the middle of the manubrium.

Inability to pass the catheter is common. The cephalic vein may terminate inches above the antecubital fossa or bifurcate before entering the axillary vein, sending a branch to the EJ vein. The cephalic vein may also enter the axillary vein at right angles, defeating any attempt to pass the catheter centrally. Furthermore, both the basilic and cephalic systems contain valves that may impede catheterization. Abduction of the shoulder may help to advance the catheter if resistance near the axillary vein occurs. The incidence of failure to place the catheter in the superior vena cava ranges from a high of 40% to a low of 2%. [70] [71] This contention is not supported by Bridges and coworkers, who found an 80% to 84% success rate with slow catheter advancement without infusion versus a 44% success rate with crystalloid infusion in supine patients. [70]

The greatest success rate (98%) reported was obtained with slow catheter advancement with the patient in a 45° to 90° upright position. [70] Flexible Bard (C. R.

Bard, Inc., Murray Hill, New Jersey) (16-ga) catheters were introduced into the basilic vein until the tip was judged to be proximal to the junction of the cephalic and basilic veins and distal to the junction of the IJ vein with the innominate vein. The wire stylet was withdrawn 18 cm, and the catheters were advanced slowly 1 cm at a time, with 2 seconds allowed between each 1-cm insertion. The natural flexibility of the

Bard catheters contributed to negotiation into the superior vena cava when the patient was upright. Obviously, this time-consuming technique is contraindicated when the patient cannot tolerate an upright position.

## ASSESSING LINE PLACEMENT

Before the infusion of fluids, the IV fluid reservoir should be lowered below the level of the patient's right atrium and the line checked for backflow of blood. The free backflow of blood is suggestive, but not diagnostic, of intravascular placement. However, backflow may occur with a hematoma or a hemothorax if the catheter is free in the pleural space. A pulsatile blood column may be noted if the catheter has been inadvertently placed into the carotid artery. Less pronounced pulsations may also occur if the catheter is advanced too far and reaches the right atrium or ventricle. Pulsations also occasionally may be noted with changes in intrathoracic pressure due to respirations, although one hopes that such pulsations will be at a much slower rate than the arterial pulse! Finally, one may attach a syringe directly to the catheter hub to check for free aspiration of venous blood. Radiographs also are indicated to verify catheter location and assess for potential complications (see below).

### Radiographs

Following the procedure, the lungs should be auscultated to detect an inequality of lung sounds suggestive of a pneumo- or hemothorax. One should obtain a chest film as soon as possible, checking for hemothorax, pneumothorax, and catheter tip position. Because small amounts of fluid or air may layer out parallel to the x-ray plate with the patient in the supine position, the film should be taken in the upright or semiupright position whenever possible. Proper catheter tip position is shown in Figure 24-17 . Misplaced catheters should be repositioned.

### Redirection of Misplaced Catheters

Misdirection of the central venous catheter is not uncommon. A number of options are available to remedy this problem. Schaefer has described a novel technique in which a 2 Fr Fogarty catheter is inserted through the lumen of the central line and advanced 3 cm beyond the tip. The entire assembly is withdrawn until only the Fogarty catheter is in the subclavian vein. One milliliter of air is injected into the balloon, and the Fogarty catheter is advanced. It is hoped that the blood flow will direct the assembly into the superior vena cava. The balloon is deflated and the central line is advanced over the Fogarty catheter, which is then withdrawn. [72]

Other manipulations with guide wires have been suggested, but often reinsertion with

another puncture is required for the misplaced catheter to be positioned properly.

**ULTRASOUND-GUIDED CENTRAL VENOUS ACCESS**

In maximizing the success and minimizing the complications of central venous access, there is no substitute for experience. However, occasional patients will present venous access challenges to the most seasoned emergency physician. Anatomic

**Figure 24-17** A chest film showing the proper catheter tip placement in the superior vena cava *(arrow)*. The tip should *not* lie within the right atrium or the right ventricle.

(skeletal or vascular) abnormalities, whether congenital and acquired, may be encountered and can thwart successful cannulation. As noted above, when time permits, a Doppler ultrasound device can be used to identify the location of major veins. The course of these vessels can be marked on the skin surface and used as an anatomic guide during needle placement. Alternatively, more sophisticated ultrasound imaging systems have been adopted for guiding venous cannulation.

The most commonly described imaging tool is a hand-held 7.5 MHz real-time mechanical sector transducer with an attached needle guide. The device is coupled with a small video display (Fig. 24-18) (Figure Not Available) . To use the instrument, the nonsterile transducer is covered with acoustic coupling gel and placed inside a sterile sheath. Additional sterile gel is placed on the skin over the site being imaged, and the unit is used to determine the location, orientation, and diameter of the target vessel. When accessing the jugular or femoral systems, this is done by placing the transducer according to traditional puncture site landmarks. Imaging the subclavian vein from the IC approach is more difficult. Gualtieri and colleagues suggest identifying the axillary vessels at their most proximal position under the distal clavicle and then following the vessels medially as they course beneath the clavicle. [73] Once the vessel is identified, the overlying skin may be marked for later venipuncture or a needle and syringe secured to the transducer for immediate cannulation. Under ultrasound guidance, the needle is advanced through the skin and SQ tissue toward the target vessel. Once the needle is in close proximity to the vessel, one will see compression of the vein. Once the vessel wall has been penetrated, the vein will refill with blood and assume its original shape. The transducer can then be detached and cannulation proceed.

**Figure 24-18** (Figure Not Available) *A,* Surface ultrasound-directed central vein identification. A handheld transducer allows noninvasive localization of veins, in this case the subclavian. The device shown includes a needle guide, which allows simultaneous visualization and penetration of a targeted vessel. *B,* Surface ultrasound image of the subclavian artery *(left)* and vein *(right). (Courtesy of Irene R. Skolnick, Dymax Corp, Pittsburgh.)*

The majority of prospective analyses of the device have examined IJ vein cannulations [74] [75] [76] and have uniformly suggested advantages to the technique. Ultrasound-guided attempts demonstrated greater overall success, as well as an increased rate of successful first punctures. Clinically significant complications were too infrequent to definitely conclude greater patient safety with the ultrasound technique; studies specifically examining complications demonstrated less frequent hematoma formation

and inadvertent arterial puncture. [73] [74] Ultrasound guidance may assume greater prominence in central venous access in the future. However, given the generally favorable success rate and low complication rate of traditional access techniques, the relative infrequency of central venous cannulation in many emergency departments, and the considerable cost of the device, the role of ultrasound imaging guidance remains uncertain.

## COMPLICATIONS

The medical literature is replete with reports of the complications of large vein venipuncture. Common complications for the different approaches are summarized in Tables 24-4 and 24-5 (Table Not Available) . Key injuries categorized by organ system and by approach are discussed in the sections that follow.

### Pulmonary Complications

Pulmonary complications of subclavian and internal jugular venipuncture include pneumothorax, hemothorax, hydrothorax, hemomediastinum, hydromediastinum, tracheal perforation, and endotracheal cuff perforation. Pneumothorax is the most frequently reported complication, occurring in up to 6% of subclavian venipunctures. [77] Initially the importance of this complication was minimized, but reports of fatalities caused by tension pneumothorax, bilateral pneumothorax, and combined hemopneumothorax followed. [78] [79] One would expect a higher incidence of pneumothorax if the procedure were performed during CPR or positive-pressure ventilation. A small pneumothorax can quickly become a life-threatening tension pneumothorax under positive-pressure ventilation. Hemothorax may occur following subclavian vein or artery laceration, pulmonary artery puncture, or intrathoracic infusion of blood. Hydrothorax occurs as a result of infusion of IV fluid into the pleural space. Hydromediastinum is an uncommonly reported complication that is potentially fatal. [80]

### Vascular Complications

Air embolism is a potentially fatal complication from any central venous cannulation. Flanagan and colleagues determined that a 14-ga needle can transmit 100 mL of air per second with a 5-cm $H_2$ O pressure difference across the needle. [81] Air embolism may occur if the line is open to air during catheterization or if it subsequently becomes disconnected. The recommended treatment is to place the patient in the left lateral decubitus position to relieve air bubble occlusion of the right ventricular outflow tract. [82] If this is unsuccessful, aspiration with the catheter advanced into the right ventricle has been advocated. [83]

Catheter embolization resulting from shearing of the catheter by the needle tip is a serious and avoidable complication. This occurs when the catheter is withdrawn through the needle or if the guard is not properly secured. It is more likely to occur when using catheters that are not permanently affixed to the catheter hub. Complications occur frequently following embolization and include arrhythmias, venous thrombosis, endocarditis, myocardial perforation, and pulmonary embolus. [84] The mortality rate in patients who did not have these catheters removed has been reported to be as high as

60%. [85] Transvenous retrieval techniques are usually attempted and followed by surgery if they are unsuccessful. [86]

Perforation or laceration of vascular structures may cause hemothorax, hemomediastinum, and volume depletion. These are rarely serious complications, but fatalities

have been reported. Surgical repair is occasionally required. [87] Arteriovenous malformation has also been reported. [88]

Perforation of the myocardium is a rare but generally fatal complication of central venous catheterization by any route. [89] The presumed mechanism is prolonged contact of the rigid catheter with the beating myocardium. [90] The catheter perforates the myocardial wall and causes tamponade either by bleeding from the involved chamber or infusion of IV fluid into the pericardium. The right atrium is involved more commonly than the right ventricle. [61] This complication can be prevented by determining the catheter tip position on a postinsertion chest film and repositioning improperly placed catheters. Cardiac tamponade can also occur with misplacement of the central venous line in the pericardiophrenic vein. [91] Premature atrial or ventricular beats may be observed if the catheter tip is in contact with the endocardium. Serious dysrhythmias do not occur, and the ectopic beats may be abolished if the catheter is repositioned.

Catheter knotting or kinking may occur if the catheter is forced or repositioned or if an excessively long catheter is used. [92] The most common result of kinking is poor flow of IV fluids. Johnson and Lazardchick reported a case of superior vena caval obstruction caused by a kinked catheter. [93]

Thrombosis and thrombophlebitis occur rarely because of the large caliber and high flow rates of the vessels involved. [57] It is important to determine that the catheter tip rests in the superior vena cava, especially during the infusion of irritating or hypertonic solutions.

[93] Thrombi may also form secondary to prolonged catheter contact against the vascular endothelium. Ducatman and colleagues reported a 29% incidence of mural thrombi in the innominate vein, superior vena cava, and right ventricle of patients who had central lines in place an average of 8 days before death. [94] However, no complications were directly attributable to these small, firmly adherent thrombi.

Thoracic duct laceration is a frequently discussed complication of left-sided subclavian venipuncture; however, it is extremely uncommon. McGoon and coworkers cite this as a complication of internal jugular cannulation but not subclavian cannulation. [77]

**Infectious Complications**

Infectious complications include local cellulitis, thrombophlebitis, generalized septicemia, osteomyelitis, and septic arthritis. [77] The incidence of septic complications varies from 0% to 25%. [95] In a retrospective audit, Herbst documented only 1 culture-proven infectious complication in 117 patients. [96] The frequency with which infectious complications are seen is directly related to the attention given to aseptic technique in insertion and aftercare of the catheter. One study suggested a higher incidence of contamination with triple-lumen catheters [97] ; however, Kelly and associates reported an acceptably low incidence of bacteremia and sepsis (3.1%) using this device. [98]

**Neurologic Complications**

Neurologic complications are extremely rare and are presumably caused by direct trauma from the needle during venipuncture. Brachial plexus palsy and phrenic nerve injury with paralysis of the hemidiaphragm have been reported. [99] [100]

**Miscellaneous Complications**

Improper catheter tip position occurs commonly. Conces and Holden reported that only 71% of subclavian catheters were located in the superior vena cava on the initial chest film. [101] Complications of improper positioning include hydrothorax, hemothorax, ascites, [102] chest wall abscesses, [103] embolization to the pleural space, [104] and chest pain. [105] More commonly, improper location yields inaccurate measurements of the CVP or is associated with poor flow caused by kinking. [106] An unusual complication caused by improper tip position is cerebral infarction. Hurwitz and Posner reported 2 patients who developed fatal cerebral infarcts following inadvertent cannulation of the subclavian artery. [107]

**Subclavian Approaches**

The claim by Moosman that the SC approach is more likely to be associated with complications is not substantiated by the medical literature. [56] In all reported series the complication rate has been low, ranging from 0% to 6%. [11] [28] [108] A compilation of the data from published series yields an overall complication rate of 1.3%. In a randomized prospective comparison of SC and IC venipuncture in 500 emergency department

patients, Sterner and colleagues reported complication rates of 2.0 and 5.1%, respectively. [109] The most significant complications have been pneumothorax and subclavian

---

*From Knopp R, Dailey RH: Central venous cannulation and pressure monitoring. JACEP 6:358, 1977.*

(Not Available)

---

artery puncture; the highest incidence of pneumothorax is 2.4%. [28] Adherence to Yoffa's technique [11] decreases the risk of these complications, because the needle is directed away from the pleural dome and subclavian artery. The relatively superficial location of the vein when approached from above the clavicle (1.5 to 3.5 cm) lessens the risk of puncture or laceration of deep structures.

Catheter tip malposition is also quite infrequent because of the more direct path to the superior vena cava. For those series in which malposition has been reported, the overall rate is 1.1%. [12] [27] [28] Fischer and coworkers noted a malposition rate of 27.6% using the IC technique. [110] The highest incidence of malposition using the SC technique is 7% and occurred during the performance of CPR. [12] In the same series, a 26% malposition rate was reported for the IC technique.

The incidence of failure to establish a functioning SC line ranges from 0% to 5%, [11] [27] [28] [111] with an overall rate of 4%. The failure rate reported for the IC technique ranges from 2.5% to 8%. [57] One death has been reported as a result of air embolism, a complication not specifically related to the SC technique. [111]

**IJ Approach**

Many of the complications of IJ cannulation are similar to those of subclavian access. Infection, catheter malposition, thrombosis, and damage to surrounding structures are complications common to all puncture sites for central venous cannulation. The reported rates of thrombosis for internal jugular vein catheterizations range from a report of no significant thrombosis in 1 study to a high of 66% of patients exhibiting some thrombosis in a study of 33 medical intensive care unit patients. [112] No reports of significant pulmonary embolus directly attributable to an IJ catheter were found. Such wide variation in the reported incidence of complications is common, in part because of the

different methods of detecting and reporting complications, variable experience

with the different techniques, and the different patient populations.

The number of complications increases, especially those due to thrombosis and infection, with longer duration of catheterization and increasing severity of the patient's illness. [16] Complications also seem to be higher with the use of the left IJ vein as opposed to the right. [47] [61] [62] Reported complications thought to be due at least in part to the use of the left-sided approach include mediastinal migration of the catheters and at least 1 instance of fatal pericardial tamponade.

One fairly common complication unique to the IJ approach is a hematoma in the neck. [32] With the IJ approach, pressure can be maintained easily on the area of swelling, and most hematomas will resolve spontaneously. If carotid arterial puncture is recognized and treated with compression, it rarely causes significant morbidity in the absence of marked atherosclerotic disease, although arteriovenous fistulas have been reported after IJ puncture. [113] Several neurologic complications unique to the IJ site of venipuncture have also been reported as a result of hematomas or of direct injury. [114] [115] These complications include damage to the phrenic nerves, an iatrogenic Horner syndrome, trauma to the brachial plexus, and even an instance of the passage of a catheter into the thecal space of the spinal canal. [116] [117] [118] [119] If the carotid artery is punctured, one may again attempt IJ or subclavian cannulation on the same side after appropriate, prolonged (15 to 20 minutes) compression.

Arterial puncture is a contraindication to attempting the IJ route on the opposite side, because bilateral hemorrhage may occur with resultant airway compromise. The physician should be prepared to rapidly intubate should this occur. Even in the face of a coagulopathy, however, the IJ approach has been found to be successful (99.3% of cases) and safe (<1% complication rate). [120]

**Femoral Approach**

Femoral lines are generally associated with less severe complications than are IJ or subclavian approaches because of the avoidance of thoracic trauma. The peritoneum can, however, be violated, with possible resulting perforation of the bowel. Bowel penetration is especially likely if the patient has a femoral hernia. [121] Injury to the bowel is likely to be minimal and is unlikely to require specific treatment. Nonetheless, the potential bacterial contamination of the femoral puncture site may pose a significant problem. Aspiration of air on placement of a femoral line necessitates removal of the catheter and reinsertion at another site. Bonadio and associates reported a case in which a patient developed clinical signs of peritonitis that were found to be due to infiltration of IV fluids into the anterior abdominal wall from a femoral catheter. [122]

A psoas abscess may result from penetration posteriorly of the underlying psoas fascia. [121] The bladder, when distended, can also be punctured during femoral cannulation, although bladder puncture is unlikely to require therapy beyond removal of the aberrantly placed catheter. Strict aseptic technique should be maintained to prevent septic arthritis in the unlikely event that the hip capsule is punctured. This complication

has been reported in infants. [123]

The most common complications of femoral venipuncture are inadvertent arterial and venous perforation. As mentioned in the Indications section, arterial puncture is more common in the patient who is in a low- or no-flow circulatory state. Emerman and colleagues reported that during cardiac arrest, the success rate for femoral catheterization was only 77%, compared with 94% for subclavian vein catheterization. [124] Prolonged (>15 minutes) pressure should stop any arterial hemorrhage in a patient with normal clotting mechanisms.

The femoral nerve can also be injured by an errant needle puncture. [120] [122] Complications can be minimized if the patient has a pulse and the femoral vein is approached medial to the femoral pulsations. A helpful mnemonic is NAVEL, which describes the anatomy of the region from lateral to medial: *n*erve, *a*rtery, *v*ein, *e*mpty space, and inguinal *l*igament. One study of 5306 femoral vein cannulations using the guide wire technique reported 5 severe complications (3 episodes of severe retroperitoneal bleeding after internal iliac artery puncture, 1 case of fatal femoral artery hemorrhage, and 1 reversible femoral nerve injury).

Getzen and Pollak, in a large study of military casualties, reported a 1.6% incidence of major hematomas, a 3.3% incidence of infection, and a 5.6% incidence of thrombophlebitis. [125] Thrombophlebitis does occur more frequently with femoral lines than with IJ and SC methods. [121] Thrombophlebitis is usually seen only with prolonged catheterization. There have been reports of pulmonary emboli in 2 of 24 patients that were thought to result from the thrombosis caused by prolonged (3 to 14 days) femoral cannulation. [126] Kanter and coworkers reported an 11% incidence of leg swelling or documented thrombosis in a series of pediatric patients. [127]

### Basilic-Cephalic Approaches

Cannulation of the central venous system through the arm veins has the lowest major complication rate of all. Superficial local infections are common (10% to 20% incidence) and rarely may lead to more serious problems, including sepsis. Catheter malposition is common, and studies have shown this to happen in 10% to 40% of placements. [128] [129] One nuisance of this type of catheter is the need to immobilize an entire extremity and the shoulder to prevent catheter movement and kinking.

## CONCLUSION

Cannulation of the central venous circulation is a necessary skill for emergency physicians. Safe application of the various techniques available requires detailed knowledge of anatomy and operative technique, as well as a healthy respect for potential complications. Inexperienced physicians should not undertake these techniques without supervision. While the IC subclavian approach is most commonly encountered in clinical practice, familiarity with the SC, IJ, femoral, and basilic-cephalic approaches will provide the emergency physician with a full complement of techniques

for gaining access to the central venous circulation under a variety of clinical demands.

## Central Venous Pressure Measurement

Although described by Forssman in 1931, it was not until the early 1960s that measurement of CVP became commonplace

as a means of assessing cardiac performance and guiding fluid therapy. [130] Clinically, CVP measurements are most frequently used as a guide for determination of a patient's volume status and fluid requirements and for investigation of tamponade. [131] [132] Critical commentaries have been written by some researchers who regard CVP monitoring as ineffective, outmoded, and unreliable. [133] The astute clinician, however, can maximize the usefulness of this diagnostic tool by careful consideration of its indications and limitations. CVP is one of many variables that must be correlated in the development of an overall management plan for the care of critically ill patients.

### PHYSIOLOGY

Simply stated, the CVP is the pressure exerted by the blood against the walls of the intrathoracic venae cava. Because the pressure in the great veins of the thorax is generally within 1 mm Hg of right atrial pressure, the CVP reflects the pressure under which blood is returned to the right atrium. [134] The pressure in the central veins has 2 significant hemodynamic effects. First, the pressure promotes filling of the heart during diastole, a factor that helps determine cardiac output. Second, the CVP is also the backpressure of the systemic circulation, opposing the return of blood from the peripheral blood vessels into the heart. [135] The CVP therefore affects both the ability of the of the heart to pump blood and the tendency for blood to flow from the peripheral veins. [26] [134] The CVP reading is determined by a complex interaction of intravascular volume, right atrial and ventricular function, venomotor tone, and intrathoracic pressure. [134]

One can measure CVP accurately by placing the tip of a pressure monitoring catheter into any of the great systemic veins of the thorax or into the right atrium. [135] Because the risks of catheter placement in the atrium include atrial perforation and cardiac dysrhythmias, any large vein within the thorax is preferred. [136] The catheter is commonly connected to an electronic pressure transducer interfaced with a monitoring system capable of calculating a mean pressure value and displaying pressure waveforms.

### INDICATIONS AND CONTRAINDICATIONS FOR CVP MEASUREMENT

The four major indications for CVP monitoring are as follows:

1. Acute circulatory failure
2. Anticipated massive blood transfusion for fluid replacement therapy

3. Cautious fluid replacement in patients with compromised cardiovascular status
4. Suspected cardiac tamponade

The procedure is contraindicated when other resuscitation therapeutic and diagnostic interventions take priority over central venous access and CVP transducer setup and calibration.

A common misconception is the incorrect assumption that CVP consistently reflects pressures found in the left side of the heart. The measurement that best reflects left ventricular pressure changes and reserve is the left atrial pressure, or the nearly equivalent pulmonary capillary wedge pressure (PCWP). The development of the flow-directed pulmonary artery catheter has allowed repeated measurements of PCWP, thus permitting accurate assessment of the left atrial pressure.

The CVP is most helpful in patients without significant preexisting cardiopulmonary disease. No consistent relationship between isolated CVP and left atrial pressure measurements has been demonstrated in patients with *significant cardiopulmonary disease.* Forrester and coworkers, in a study of 50 patients with myocardial infarction, demonstrated that CVP measurements had no consistent relationship to PCWP. [137] James and Myers studied 3 parameters--CVP, pulmonary arterial pressure, and PCWP--in 116 patients who either were in shock or had undergone major surgery. [138] In 76 of 116 instances, the PCWP differed significantly from the CVP. An early rise in the PCWP was noted before the rise in CVP. Samii and coworkers [133] studied 13 relatively elderly patients (mean age, 62 years) without obvious cardiopulmonary disease and found a disparity between the right and left ventricular filling pressures. They concluded that CVP may be a misleading index for predicting the PCWP in elderly patients.

Toussaint and associates reported a significant correlation between CVP and PCWP in 14 patients with no prior history of cardiopulmonary disease. [139] Yet in the same study, a poor correlation between CVP and PCWP was shown in 13 patients with a history of cardiopulmonary disease. Interestingly, Rajacich and colleagues found that CVP accurately predicted left atrial pressures in 17 cardiac bypass graft patients, even in the setting of high positive end-expiratory pressure. [140] Their patients had well-preserved cardiac function and normal valvular function. These findings suggest that CVP provides a reliable assessment of cardiac function only in the absence of cardiopulmonary disease.

**PROCEDURE**

Although CVP may be determined with a manometry column assembled at the bedside (Fig. 24-19) , the most common technique in practice is measurement with an electronic transducer interfaced to a monitoring system (Fig. 24-20) . Typical transducers include a nipple valve attached to a pressurized bag of saline to allow easy flushing of the system. To use these manometers, the transducer is attached to the patient's central line with a length of flexible yet fairly rigid-walled tubing filled with saline. A three-way stopcock is placed between the patient and the transducer to simplify line flushing and calibration.

All air bubbles are flushed from the system by opening the stopcock to air and flushing saline through the line. Air bubbles should not be flushed into the patient. Even tiny bubbles left in the tubing will dampen the CVP wave and potentially cause underestimation of venous pressure.

After the system has been flushed, the stopcock (with the transducer still open to air) is placed at the level of the patient's tricuspid valve. The monitor detecting the transducer's signal is then "zeroed," or calibrated. The transducer is calibrated at the level of the tricuspid valve, which can be approximated on the skin surface as a point at the midaxillary line and fourth intercostal space. [134] Finally, the stopcock

**Figure 24-19** *A,* Simple manometry column used to measure CVP at the bedside. The stopcock is turned to direct the flow to the patient, bypassing the manometer. This is the position that is maintained to keep the catheter patent. The tubing is always flushed before connecting it to the patient's central venous pressure catheter. *B,* The stopcock is turned to fill the manometer to 25 cm $H_2O$. *C,* The stopcock is opened to the patient, and the column of water in the manometer is allowed to fall and stabilize before a reading is taken. Note that the zero mark is horizontally aligned with the tricuspid valve (midaxillary line in a supine patient).

**Figure 24-20** General configuration of an intravascular pressure transducer. A working understanding of these devices, particularly as regards proper setup, zeroing, and line debubbling, will maximize their effectiveness and accuracy.

is set so that the transducer is in continuity with the patient's venous catheter.

In spontaneously breathing patients, readings should be taken at the end of inspiration of a normal breath. If the patient is receiving positive-pressure ventilation, the CVP changes during the respiratory cycle are reversed, rising with inspiration and decreasing with expiration. In these patients, readings should be taken near the end of expiration. [141] Thus, during both normal and mechanical ventilation, the lowest reading is a useful estimate of the mean CVP.

A reading may be taken after proper assembly of the equipment and after accurate placement of the tip of the catheter has been established. To ensure optimal measurement, the patient should be in the supine position. Whenever the patient is repositioned, care must be taken to ensure that the transducer has been recalibrated to reflect the new position of the patient.

## ERRORS IN CVP MEASUREMENT

A number of extrinsic factors may alter the accuracy of the CVP reading (Table 24-6) . [26] In addition to the position of the patient, these include changes in intrathoracic pressure, [142] catheter tip malposition, obstruction of the catheter, and failure to calibrate or zero the line. Activities that increase intrathoracic pressure, such as coughing or

straining, may cause spuriously high measurements. The patient should be

<table>
<tr><td align="center">**TABLE 24-6** -- Faulty Central Venous Pressure Readings</td></tr>
<tr><td>Increased intrathoracic pressure (ventilator, straining, coughing)<br>Reference points in error<br>Malposition of catheter tip<br>Blocking or ball-valve obstruction of catheter<br>Air bubbles in circuit<br>Readings during wrong phase of ventilation<br>Readings by different observers<br>Vasopressors (presumed)</td></tr>
</table>

relaxed at the time of the measurement and breathing normally. Positive-pressure ventilation raises the CVP reading by only 1 to 3 cm $H_2O$. If disconnection from the ventilator can be tolerated, the patient should be temporarily disconnected to provide a more reliable measurement.

Another reason for faulty readings is malposition of the catheter tip. If the catheter tip has not passed far enough into the central venous system, peripheral venous spasm or venous valves may yield pressure readings that are inconsistent with the true CVP. [26]

If the catheter tip is passed into the right ventricle, a falsely high CVP is obtained. Recognition of a characteristic right ventricular pressure waveform on the patient's monitor should hopefully preclude this error. Such fluctuations may occasionally be seen in appropriately positioned CVP lines when significant tricuspid regurgitation or atrioventricular dissociation (cannon a waves) are present.

Inaccurate low venous pressure readings are seen when a valve-like obstruction at the catheter tip occurs either by clot formation or by contact against a vein wall. As mentioned above, wave damping due to air bubbles in the transducer or tubing also leads to faulty readings.

Using poorly zeroed lines may result in inaccurate measurements that may be interpreted as a change in the patient's status when none has actually occurred. The transducer should be zeroed to the same level for every measurement.

Some investigators mention a falsely elevated CVP in patients who are receiving vasopressors, but controlled data on this aberration are lacking. One animal study suggests that fluid can be infused into 1 lumen of a multilumen catheter without affecting the CVP reading at another lumen. [143]

**INTERPRETATION OF THE CVP MEASUREMENT**

Because determination of the CVP can aid the clinician in assessment of the critically ill patient, it is paramount that the clinician know the normal values and the variables that may affect these values and recognize the pathologic conditions that correlate with abnormal values.

Although early articles reported varying normal ranges for CVP measurements, recent cardiac catheterization studies have demonstrated that the normal range extends from -2 to +7 cm $H_2O$.

Gowen reports from his clinical experience that a reading of 7 cm $H_2O$ is the upper limit of normal, and a reading of 8 to 10 cm $H_2O$ is a borderline elevation, whereas levels >12 cm $H_2O$ are consistent with impending heart failure. [144] Weil and coworkers, however, described the normal CVP as ranging from 2 to 10 cm $H_2O$ and considered a high CVP to be >15 cm $H_2O$. [132] Knobel and associates noted that a CVP <6 cm $H_2O$ is rarely associated with a PCWP >12 cm $H_2O$ in septic patients. [145] The following guideline reflects the consensus of the literature:

*Low:* <6 cm $H_2O$

*Normal:* 6 to 12 cm $H_2O$

*High:* >12 cm $H_2O$

In the late stages of pregnancy (30 to 42 weeks), the CVP is physiologically elevated, and normal readings are 5 to 8 cm $H_2O$ higher in pregnant than in nonpregnant women.

A CVP reading <6 cm $H_2O$ is consistent with low right atrial pressure and reflects a decrease in the return of blood volume to the right heart. This may indicate that the patient requires additional fluid or blood. A low CVP reading is also obtained when vasomotor tone is decreased, as in sepsis, spinal cord injury, or other forms of sympathetic interruption. [132] [144] [145]

A CVP reading falling within a normal range is viewed in relationship to the clinical situation. A reading >12 cm $H_2O$ indicates that the heart is not effectively circulating the volume presented to it. This situation may occur in the case of either a normovolemic patient with cardiac decompensation or a patient with a normal heart who is overhydrated and overtransfused. A high CVP is also related to variables other than pump failure, which include pericardial tamponade, restrictive pericarditis, pulmonary stenosis, and pulmonary embolus. [144]

Changes in blood volume, vessel tone, and cardiac function may occur alone or in combination with one another; therefore, it is possible to have a normal or high CVP in the presence of normovolemia, hypovolemia, and hypervolemia. One must interpret the

specific CVP values with respect to the entire clinical picture: the response of the CVP to an infusion is more important than the initial reading.

**Fluid Challenge**

Monitoring of the CVP may be helpful as a practical guide for fluid therapy. [131] [132] Serial CVP measurements provide a fairly reliable indication of the capability of the right heart to accept an additional fluid load. Although the PCWP is a more sensitive index of left heart fluid needs (and in some clinical situations, PCWP measurement is essential), serial measurement of CVP can provide significant information.

A fluid challenge can help assess both volume deficits and pump failure. Although a fluid challenge can be used with either PCWP monitoring or CVP monitoring, only the fluid challenge for CVP monitoring is discussed here. Slight variations in methodology of fluid challenge are reported in the literature. Generally, aliquots of 50 to 200 mL of crystalloid are sequentially administered, and measurements of CVP levels are obtained after 10 minutes. [111] [144]

The fluid challenge is generally carried out in the following manner [132] : Fluid is administered by a route other than that used for monitoring. An initial CVP reading is taken, and fluid is infused at a rate of 20 mL/min over a 10-minute period. The infused volume is allowed to equilibrate for 10 minutes, and a reading is taken. If the CVP is >5 cm of $H_2O$ over the initial measurement, the fluid challenge is discontinued, and one assumes that the right ventricle is unable to handle an additional fluid load. Increases of between 3 and 5 cm $H_2O$ over the initial CVP value are equivocal, and additional measurements are taken over the next 30 minutes if this reading is obtained. Increases of <2 cm $H_2O$ over the original reading or a return of higher readings to this level within 30 minutes is indicative of volume depletion. The fluid challenge is repeated until measurements indicate that adequate volume expansion has occurred. The fluid challenge is discontinued as soon as hemodynamic signs of shock are reversed or signs of cardiac incompetence are evident.

**Cardiac Tamponade**

In cardiac tamponade, pericardial pressure rises to equal right ventricular end-diastolic pressure. The pericardial pressure encountered in pericardial tamponade characteristically produces an elevated CVP. The degree of CVP elevation is variable, and one must interpret measurements cautiously; CVP readings in the range of 16 to 18 cm $H_2O$ are typically seen in acute tamponade, [132] [146] but elevations of up to 30 cm $H_2O$ may be encountered. The exact CVP reading is often lower than one might intuitively expect, and it is not uncommon to encounter tamponade with a CVP of 10 to 12 cm $H_2O$. A normal, or even low, CVP reading may be seen if the tamponade is associated with significant hypovolemia.

An excessive rise in CVP following fluid challenge may be more important than a single reading in the diagnosis of pericardial tamponade. It is interesting to note that Shoemaker and associates [146] reported a decrease in CVP just before cardiovascular

collapse in patients with pericardial tamponade.

Excessive straining, agitation, pneumatic antishock garment inflation, positive-pressure ventilation, or tension pneumothorax may increase intrathoracic pressure, producing a high CVP reading, and may erroneously suggest the diagnosis of pericardial tamponade. Increases in vascular tone, as seen with the use of dopamine or other vasopressors, may also elevate the CVP, mimicking tamponade and complicating volume estimation.

**CONCLUSION**

CVP monitoring provides useful hemodynamic monitoring information in those individuals with a relatively normal cardiopulmonary system who do not otherwise warrant PCWP monitoring.

# Chapter 25 - Accessing Indwelling Lines

**John M. Howell**

Many therapies require the use of intravenous (IV) catheters that afford indwelling access to the central circulation. Indwelling central venous access is essential to those who require lengthy chemotherapy, [1] [2] hyperalimentation, [3] [4] extended antimicrobial therapy, [5] and hemodialysis. [6] [7] [8] An ever-increasing number of individuals care for these devices as outpatients. More than 500,000 indwelling venous access devices are placed annually in the United States. [9] These devices make indwelling lines available to emergency department staff to draw blood and administer medications, blood products, and IV fluids with minimal patient discomfort. Furthermore, an awareness of attendant complications should help minimize the risk of line sepsis and central vein thrombosis.

## BACKGROUND

### Historical Features

In 1973, after unsuccessful efforts with arteriovenous shunts, Broviac designed an IV catheter that afforded prolonged access for hyperalimentation patients. [3] This Silastic catheter was 90 cm long and passed through the subclavian vein to the mid-right atrium. Broviac's initial description fashioned a template for several products in use today.

Hickman altered Broviac's prototype in 1979 [1] for the treatment of leukemia patients receiving chemotherapy (Fig. 25-1) . His modified catheter was larger in diameter and lacked a surrounding sheath. This bigger lumen facilitated the drawing of blood as well as the infusion of chemotherapeutic agents, blood, and IV solutions. More recent approaches to the dilemma of prolonged access include multilumen external catheters [10] and surgically implanted subcutaneous infusion devices (e.g., Port-A-Cath, Infuse-A-Port, and MediPort). [11] These products are beneficial in that they obviate the need for multiple peripheral IV lines; however, their use may lead to complications. Wound sepsis and central venous thrombosis are among the more common difficulties encountered by patients tending their catheters at home. [5] [12] Timely recognition of these complications may avert morbidity in a population composed largely of immunocompromised individuals.

### Patient Populations with Indwelling Lines

Central venous and right atrial catheters are commonly placed in patients with cancer to deliver chemotherapy and to prevent tissue infiltration of these destructive chemicals. [11] [13] They are useful in treating both hematologic and solid malignancies and have been placed to facilitate daily radiation therapy of brain tumors in children. [14] Many patients opt for local care at home and return only periodically to a clinic or hospital for IV chemotherapy.

Otherwise healthy individuals with soft tissue or bony infections receive IV antimicrobials

in the same manner. Alternative indications include ambulatory heparin therapy [15] and parenteral hyperalimentation, [3] especially in those with short bowel syndrome and malnutrition. [4] McDowell and colleagues [7] and Schanzer and associates [8] reported good results using double-lumen, cuffed central venous catheters as an alternative to arteriovenous shunts in patients who need long-term hemodialysis.

Although the predominant indication for arteriovenous fistulas and shunts is hemodialysis, [15] these devices have also been used for parenteral hyperalimentation and chemotherapy. [16] However, right atrial catheters are more widely accepted for parenteral hyperalimentation and chemotherapy owing to their ease of insertion and the ability of patients to self-administer medications at home. Subclavian Uldall [17] [18]

**Figure 25-1** Hickman double-lumen catheter (12 Fr), injection caps (2), attached clamps (2), sheath introducer with vessel dilator, syringe, and 33-cm tunneler.

or Manhurkar catheters (also called *Quinton* catheters) are frequently positioned to deliver hemodialysis for up to 8 weeks while a peripheral fistula matures.

## INDWELLING CATHETER, SHUNT, AND FISTULA DEVICES

The majority of techniques designed to allow prolonged IV access form the following categories: long-term venous access catheters; implantable venous access devices; percutaneous multilumen catheters; and methods to deliver hemodialysis, including arteriovenous shunts, fistulas, and specific catheters.

### Long-Term Venous Access Catheters

Long-term venous access catheters are made by several manufacturers and include Broviac, Hickman, Leonard, Raaf, and Hermed catheters (see Fig. 25-1) . These Silastic catheters are between 65 and 90 cm long and have 1, 2, or 3 lumina. They are positioned in the right atrium either during an operation or at the bedside. [7] [11] [15] Access to the central circulation is achieved by various methods, including cephalic, [19] external jugular, [14] [15] saphenous, [15] internal jugular, [14] brachiocephalic, [20] subclavian, [15] [21] and translumbar [4] approaches. They are generally tunneled subcutaneously from the venous access point to a position on the anterior chest wall. Many kits include a 33-cm tunneler to pull catheters through subcutaneous (SQ) tissues. A Dacron cuff is generally positioned midcatheter to anchor and prevent the spread of infection. [15] CR Bard, Inc. (Salt Lake City, Utah) produces a catheter (VitaCuff) with two SQ cuffs to release silver ions that block the inward spread of microorganisms.

Two kinds of Silastic, long-term venous access catheters are neither tunnelled nor cuffed. [22] Long-term, peripherally inserted central catheters (PICCs) are placed in the brachium and terminate in the superior vena cava. They are positioned either at the bedside or under fluoroscopy. Short-line central venous catheters are placed directly into the subclavian vein. One study identified a $7 million annual savings for the insertion and maintenance of nontunneled Silastic catheters compared with tunneled

catheters. [22]

Manufacturers produce right atrial catheters in various lengths and diameters. [15] Single-lumen Broviac catheters are popular for children and vary in size from 2 to 6 Fr. Many Hickman catheters provide a double-lumen alternative up to No. 19 Fr. Weese and Trigg [23] produced a triple-lumen variation by placing Hickman and double-lumen Raaf catheters through the same venotomy. Individual lumen widths in double-lumen devices vary between 0.7 and 1.6 mm. Repair kits are available (Evermed, Inc.) that include silicone adhesive and a 12 Fr catheter segment (Fig. 25-2) .

Home care of long-term venous access catheters is generally performed on a daily basis. [15] The skin site is cleansed with alcohol and povidone-iodine before applying a sterile dressing (e.g., Tegaderm). Two to 3 mL of 100 units/mL heparin are then flushed to prevent catheter thrombosis. [15] [24] [25] The injection cap is changed weekly after first clamping the catheter. [15] Breaks in sterile procedure or overlooking the heparin flush may result in thrombosis or line sepsis.

Groshong catheters (CR Bard, Inc., Salt Lake City, Utah) are similar to Broviac and Hickman catheters in that Groshong

**Figure 25-2** Hickman catheter repair kit, with tube of adhesive, 18-ga needle, plastic syringe, injection caps (2), Luer-Lok caps (2), and external catheter segment with attached clamps.

lines are Silastic with an SQ cuff and up to three lumina. The catheter tip is closed, and there is a pressure-sensitive, two-way valve on the adjacent lateral wall (Fig. 25-3) (Figure Not Available) . There is no backflow of blood into the catheter because venous pressure maintains the valve in a closed position. Consequently, clamping and frequent heparin flushing are not necessary. The externalized part of the catheter is removable, making insertion and replacement simpler. Groshong catheters are three to seven times more likely than Hickman catheters to suffer valve-related complete catheter malfunction. [26]

**Implantable Venous Access Devices**

Implantable venous access devices (Port-A-Cath, Infus-A-Port, MediPort, MRI Port, and Norport) are surgically implanted

**Figure 25-3** (Figure Not Available) The Groshong catheter tip. The Groshong has a patented three-way valve that opens outward for infusion *(A)*, opens inward for aspiration *(B)*, and remains closed when not in use *(C). (Courtesy of Bard Access Systems, Inc., Salt Lake City, Utah.)*

circular, SQ chambers in continuity with a central Silastic catheter (Fig. 25-4) . [11] [15] [27] [28] All of these products use metallic chambers except the MRI Port, which is safe for magnetic resonance imaging (MRI) examinations. The major difference between this and other systems is that access to implantable venous access devices is obtained by inserting a tapered Huber needle through the skin into a diaphragm approximately 7 to 11 mm in diameter (Fig. 25-5) (Figure Not Available) . [15] The chamber is palpable as

well as visible on the anterior chest wall. Catheter widths are between 2.2 and 2.8 mm. [15]

In contrast to long-term venous access catheters, implantable venous access devices are accessed through a 19- or 22-ga tapered (Huber) needle to limit cylinder damage. [15] Although this technique allows approximately 2000 punctures, [15] it also hinders rapid delivery of blood and blood products. Implantable venous access devices are initially more expensive than long-term venous access catheters: however, they also require less frequent home care. Weekly or monthly [15] [24] flushing with 4 to 5 mL of heparin (1000 units/mL) prevents thrombosis.

## Percutaneous Multilumen Catheters

Triple-lumen catheters (Arrow) are inserted percutaneously into the central circulation to allow phlebotomy and simultaneous delivery of medication and blood products. They are approximately No. 7 Fr in caliber and deliver these substances through 16- and 18-ga lumina. Drawbacks include daily wound care, heparinization, and relative brevity of use. For a triple-lumen catheter, changing the line over a guide wire increases the risk of bacteremia, although moving the triple lumen to another site increases the frequency of mechanical malfunction. [29] Multilumen catheters are usually left in place <3 weeks, [10] [15] but extended use may approach several months. [15] In contrast, Hickman catheters have been left in place for 474 days, [30] and Port-A-Cath catheters up to 351 days. [27]

**Figure 25-4** Tapered Huber needle, Port-A-Cath reservoir, and catheter segment.

**Figure 25-5** (Figure Not Available) Port-A-Cath system. The Port-A-Cath system is accessed by inserting a Huber needle through the skin and portal septum. *(Courtesy of Pharmacia Nutech, Pharmacia Laboratories, Piscataway, New Jersey.)*

## Implantable Venous Access Pump Devices

Internal pump devices (Infusaid, Pfizer Hospital Products Group, Norwood, Massachusetts; SynchroMed, Medtronics, Minneapolis, Minnesota) deliver medications from the pump through a catheter into central veins, the spinal canal, and selected vessels near target organs or tumors (Fig. 25-6) (Figure Not Available) . Some devices are programmable for specific infusion rates; others are not. The catheter is accessed at its pump attachment for emergency infusion and blood drawing. Like a shunt or fistula, these devices are not used for routine, nonemergent indications.

## Arteriovenous Shunts, Fistulas, and Catheters

Arteriovenous shunts are external Silastic bridges between the arterial and venous circulations. When placed in extremities, they facilitate hemodialysis during acute renal insufficiency and failure. [15] However, subclavian and femoral vein access have recently subverted the use of these shunts in intensive care units during management of hemorrhagic shock and sepsis. In addition, central venous catheters are now used

frequently as a temporizing measure until permanent arteriovenous access sites mature. Consequently, emergency physicians are less likely to encounter arteriovenous shunts in their daily routine.

Peripheral arteriovenous fistulas, on the other hand, represent the procedure of choice for permanent vascular access in end-stage renal disease. [15] They are produced by anastomosing the peripheral venous and arterial circulations. In this way a superficial, dilated vein serves as a permanent access site for large-bore hemodialysis needles. Vessels commonly used for fistulas are the radial artery and cephalic vein or the ulnar artery and basilic vein. [15] Patent fistulas, generally located near the wrist, are easily discerned by their characteristic bruit and thrill. Pathologic arteriovenous

**Figure 25-6** (Figure Not Available) Implantable infusion pumps are available that allow for infusion of a medication at a constant rate or at a variable or programmable rate. They are normally placed in a subcutaneous pocket either in the abdomen or anterior chest wall. Two examples are shown. The Infusaid M400 Constant Flow Implantable Pump (Pfizer, Norwood, Massachusetts) *(A)* provides for a constant infusion rate of a medication placed transcutaneously into its drug chamber. It also has a sideport for direct access to the catheter for direct, percutaneous injections or IV therapy using the patient's central venous catheter attached to the device. The SynchroMed Infusion Pump (Medtronic, Minneapolis, Minn) *(B)* can be programmed by a computer through a radio transmitter for a wide variety of infusion rates. *(Courtesy of Pfizer Hospital Products Group, Norwood, Massachusetts).*

fistulas have been inadvertently produced by penetrating vascular injury [31] and superficial phlebotomy. [32]

Large-bore Uldall catheters [17] [18] are generally placed in the subclavian vein and provide hemodialysis access for up to 8 weeks while a peripheral arteriovenous fistula site matures. These double-lumen catheters are tunneled subcutaneously and lack the Dacron cuff present on most central venous access catheters. They are capped after each dialysis treatment with approximately 2500 units of heparin in each luminal arm.

Manhurkar (Quinton) catheters (Quinton Instrument Company, Seattle) are double-lumen lines inserted percutaneously into the subclavian or femoral vein for short-term dialysis access. Following insertion, each arm is flushed with 10 mL of normal saline. Subsequently, 1500 units of heparin (e.g., 1.5 mL of 1000 units/mL) are instilled into each arm.

## INDICATIONS AND CONTRAINDICATIONS

### Emergency Department Access

Indications for accessing right atrial and multilumen catheters in the emergency department include phlebotomy and administration of IV fluids and medications. In the emergency department, arteriovenous fistulas, shunts, and Uldall and Manhurkar catheters are accessed only in true emergency situations, because infection and shunt malfunction may result and necessitate additional surgical procedures to obtain access for hemodialysis. The emergency physician may be called on to free occluded lines or repair leaking external catheters; these procedures are discussed under Complications below. Right atrial and multilumen catheters should not be accessed in the emergency

department if patency cannot be demonstrated using the maneuvers described under Procedures.

**Medication Issues**

Medications that are known to be incompatible when mixed (e.g., calcium and bicarbonate) should not be administered concurrently, even through separate lumina of multilumen catheters (Arrow, personal communication, 1992). Medications should not be delivered through indwelling lines without intercurrent normal saline flushes. Arteriovenous fistulas, shunts, and Uldall catheters are used only in emergency situations in which more standard methods of IV access are not possible.

Taylor and Taylor [25] state that diazepam and diphenylhydantoin crystallize on contact with the silicone catheter walls of long-term venous access catheters and implantable venous access devices, thereby necessitating catheter replacement. In contrast, the manufacturers of these devices (i.e., Evermed, Pharmacia) hold that crystallization does not occur and that the silicone catheter wall absorbs these drugs without damage or the need for removal.

Adjacent skin cleansing with acetone or tincture of iodine products is injurious to catheter walls (Evermed, personal communication) and should not be used topically in the area of right atrial or triple-lumen catheters. However, povidone-iodine and alcohol are perfectly acceptable.

# EQUIPMENT FOR ACCESS

Access to indwelling lines requires sterile technique and appropriate precautions for prevention of exposure to bloodborne pathogens. The following items are recommended for each approach: sterile gloves, mask, and eyewear; povidone-iodine solution (10%); and sterile drapes. Additional items for specific catheter systems are identified below. For occluded catheters that do not respond to simple maneuvers (including a saline or a heparin flush), the use of thrombolytic agents as described below may be needed.

**Long-Term Venous Access Catheters**

For long-term venous access, clinicians should use catheters attached to implanted pumps only in emergencies. [25] Items needed are as follows:

1. One 10-mL syringe filled with normal saline
2. One 10-mL syringe containing 5 mL of heparin solution (100 U/mL) (5 to 20 mL of normal saline for Groshong catheters)
3. One catheter clamp or hemostat without teeth (do not clamp Groshong catheters)
4. Fluids and medications to be administered

**Implantable Venous Access Devices**

Implantable venous access devices [25] require the following:

1. One 10-mL syringe filled with normal saline
2. One 10-mL syringe containing 5 mL of heparin solution (1000 U/mL)
3. Two Huber needles with a 90° bend (19, 20, or 22 ga) or, in an emergency, a standard 19-ga needle
4. Extension tubing with a slide clamp
5. 4 × 4-inch gauze and 1-inch silk tape adequate to reinforce and stabilize the Huber needle
6. Fluids and medications to be administered

### Percutaneous Multilumen Catheters

The following items are needed with percutaneous multilumen catheters, [25] including Uldall and Manhurkar catheters:

1. One 10-mL syringe filled with normal saline
2. One 10-mL syringe containing 5 mL of heparin solution (100 U/mL) for Uldall catheters and one 10-mL syringe containing 3 mL of heparin solution (1000 U/mL) for Manhurkar catheters
3. Three standard needles (18, 19, or 20 ga)
4. Fluids and medications to be administered

### Arteriovenous Fistulas and Shunts

Arteriovenous fistulas and shunts, which are used for access only in emergencies, require the following:

1. Standard large-bore needles and IV catheters
2. Two 10-mL syringes
3. Fluids and medications to be administered

## PROCEDURES

### Accessing Long-Term Venous Access Catheters

Sterile technique is desired at all times when accessing indwelling lines. [24] The catheter (with the exception of Groshong catheters) is first clamped to prevent air embolism. Patients usually carry their own clamps; however, a hemostat without teeth will suffice. In an emergency, sterile tape or tubing wrapped around the teeth of a hemostat also protects the catheter. The cap is removed, and a 10-mL syringe of sterile water or normal saline is attached. Three to 5 mL of solution are injected and then withdrawn to ensure patency. More pronounced aspiration may be necessary to ensure patency of Groshong catheters. This procedure is done slowly with a syringe at least 10 mL in

volume to avoid damage to the cap area. [25]

Phlebotomy is accomplished by withdrawing dead space solution, reclamping, and using a separate syringe to remove the desired amount of blood. [25] Bolus medications are then injected and IV solutions infused through the catheter, which is clamped whenever unattached. A 5-mL normal saline flush should be delivered between medications. On completion, 3 to 5 mL of heparin (100 units/mL) are injected, the line is clamped, and the cap is repositioned. [15] [25] Groshong catheters should not be flushed with heparin, but instead should be flushed briskly with 5 to 20 mL of saline.

Difficulty in drawing blood from a long-term venous access catheter may be due to catheter position, catheter malfunction, or a fibrinous clot on the catheter tip. [25] Maneuvers to facilitate blood flow include the Valsalva maneuver, the reverse Trendelenburg position, slight tension on the catheter, IV hydration, and having the patient extend his or her arm above head level. [24] [25] Overzealous withdrawal on the syringe will collapse the catheter and make demonstration of patency difficult. [15] If these measures are unsuccessful, a fibrin sheath may be present on the catheter tip. Instilling 3- to 5-mL of heparin (10 or 100 units/mL) followed after several minutes by gentle aspiration is often successful in dislodging a clot. Haimov [15] reported no clinical pulmonary emboli after 70 attempts at declotting with a heparin flush. Streptokinase [15] [33] or urokinase [15] [25] are reasonable next steps. One mL of urokinase (5000 units/mL) may be injected and aspiration attempted after a 10-minute interval. [15] [25] This procedure may be repeated once. A urokinase flush successfully declots the line in up to 95% of cases. [15]

For implanted venous access pumps, access the catheter at its pump attachment for emergency infusion and blood drawing.

**Accessing Implantable Venous Access Devices**

The procedure for accessing implantable venous access devices is unique, because these devices are not external. Instead, a circular reservoir (cylinder) lies subcutaneously on the anterior chest wall. The cylinder is first palpated, and the overlying skin is prepared with povidone-iodine solution. A 10-mL syringe filled with sterile water or normal saline is attached to connecting tubing, which in turn is applied to a 19- to 22-ga, 90° tapered (Huber) needle. A clamp should be applied to the connecting tubing whenever the system is open. Air is expelled, and the Huber needle is inserted through the reservoir septum. The needle is inserted slowly and steadily through the diaphragm to the back of the reservoir. Although incomplete perforation of the septum will block flow, substantial pressure also may damage the back of the device. The clamp is removed slowly, and 5 mL of solution is injected to ensure patency. If patency is not easily demonstrated, the same measures described under Accessing Long-Term Venous Access Catheters may be used, including positioning, Valsalva maneuver, heparin flush, and low-dose thrombolytic therapy. [15] [25]

Once the solution has been injected, gentle negative pressure is applied to demonstrate the backflow of blood.

The Huber needle is then stabilized by building 4- × 4-inch gauze about the needle and further reinforcing with 1-inch silk tape. Phlebotomy is performed through the extension tubing after first removing 8 to 9 mL of blood with a separate syringe. IV solutions may also be delivered through extension tubing, although the rate of flow will be limited by the Huber needle's radius. A standard 19-ga needle may be used in emergency circumstances; however, one risks shortening the device's lifetime. A 5-mL normal saline flush should be delivered between medications. The procedure is completed with a 3- to 5-mL heparin (1000 units/mL) flush [25] and removal of the Huber needle.

## Accessing Percutaneous Multilumen Catheters

Percutaneous multilumen central catheters are used infrequently by outpatients. They are usually placed in the subclavian vein to facilitate patient comfort. One port is available for each lumen, and after povidone-iodine preparation is completed, access is gained by either inserting a needle or syringe into the protective cap or removing the cap entirely. A 5-mL normal saline or sterile water flush and verification of backflow precede all subsequent procedures. Phlebotomy is performed through the proximal 18-ga lumen to prevent mixture with medications being delivered through the other two ports. The proximal lumen port of the Arrow multilumen catheter is white and is the longest of the three tails. Tails attached to the more distal lumina are blue and brown. IV infusions are delivered in similar fashion, and a normal saline flush is injected between medications. The procedure is terminated with a 3- to 5-mL heparin (100 units/mL) flush.

## Accessing Arteriovenous Fistulas, Shunts, and Catheters

Arteriovenous fistulas, shunts, and Uldall and Manhurkar catheters are placed in patients who require hemodialysis and represent the sole access for that purpose. Consequently, routine use of these sites for phlebotomy and fluid administration is condemned. In fact, venipuncture of any type in the same extremity as a patent arteriovenous fistula is not recommended. When standard IV access cannot be obtained under emergency circumstances, however, fistulas, shunts, and catheters may all be used to administer IV solutions and medications. If possible, fistula patency should first be ascertained by noting a bruit and palpable thrill, although these signs may not be appreciable if the patient is in extremis.

Prepare the area with povidone-iodine solution and access the fistula with the smallest gauge needle appropriate to the task. [34] Puncture 1 to 2 cm from the anastomosis ends nearest the venous side, and avoid aneurysmal sites. [34] When complete, monitor the area for hemorrhage, and apply local pressure to avoid significant bleeding. Arteriovenous shunts are accessed similarly by placing the smallest needle possible into the catheter, bridging arterial and venous circulations. Local pressure should be applied for 5 minutes after completing the procedure. Uldall catheters are used in much the same way that multilumen central catheters are accessed. The retaining cap on each arm may be either removed or injected. Up to 5000 units of heparin are present within the two lumina, and so it is imperative that aspiration be performed before administering fluid or medications. Manhurkar catheters are accessed in a similar manner. After use,

flush each catheter arm with 10 mL of normal saline and instill 1.5 mL of heparin solution (1000 units/mL) into each catheter arm.

## AFTERCARE INSTRUCTIONS

Before release from the emergency department, each patient should be reminded of those aspects of catheter care that prevent complications and prolong the device's lifetime. [25] Patients with implantable venous access devices should avoid direct pressure on the reservoir and report local bruising or bleeding immediately. Although these patients may bathe and swim normally, heparin flushes are essential to prevent thrombosis in patients with these indwelling devices.

Long-term venous access catheters and multilumen catheters are sterilely dressed and flushed on a routine basis, [25] and patients should never force the delivery of heparin. Tunneled (e.g., Hickman) and nontunneled (e.g., PICC) catheters are flushed twice each week with 5 mL of heparin (10 units/mL). Implantable venous access devices are flushed every 4 weeks with heparin. Generally, Groshong catheters are flushed with 5 mL of saline once a week. Manhurkar and Uldall catheters are "flushed" during dialysis. Manhurkar catheters also are used for pheresis, in which case they are treated three times a week with normal saline and heparin as described above. An inability to flush any indwelling catheter should be reported immediately to a physician. All indwelling catheters must be observed daily for bleeding and signs of infection, which include fever, pain, redness, swelling, and purulent drainage.

## COMPLICATIONS (Table 25-1)

### Complications of Emergency Department Access

Line sepsis, discussed in more depth later, occurs when sterile technique is not strictly maintained. [24] [25] [35] Gloves, mask, and goggles should be donned before accessing indwelling lines and arteriovenous fistulas. Also, maintaining a closed system by clamping the catheter appropriately prevents the delivery of air into the venous circulation. Air embolism [36] is heralded by tachypnea, hypotension, and coma. When air embolism is suspected clinically, the patient should be positioned on the left side in the Trendelenburg

| **TABLE 25-1** -- Complications of Accessing Indwelling Lines in the Emergency Department |
| --- |

| Displacement of catheter | |
| Cardiac dysrhythmias | |

position, and supportive measures, including high-flow oxygen and secure IV access, should be undertaken.

The externalized portion of a right atrial catheter may be cut with scissors [5] or perforated during clamping, especially if an improper clamp is used. [36] The catheter should be reclamped immediately between the patient's skin and the location of the catheter injury (except for Groshong catheters). [25] At this point an alternate method of IV access may be sought. Repair kits (e.g., Evermed) for externalized catheters are available that contain silicone adhesive, plastic clamps, injection caps, and a 12 Fr catheter replacement segment (see Fig. 25-2) . Familiarity with this technique is necessary to avoid further problems (see below).

Embolization of catheter thrombi during flushing and injection of solutions is a concern. Anderson and colleagues [12] prospectively evaluated the size and frequency of catheter thrombi in 43 patients by aspirating after a urokinase flush. Clots were noted in 40 of 43 subjects and 153 of 508 total specimens. Thrombi varied in size from small fragments to 5 cm in length. No clinical sequelae were noted; however, the investigators discuss the potential for pulmonary embolism. Haimov [15] reported no clinical pulmonary emboli after heparin flushes in 70 patients; however, Zureikat and associates reported 1 case of pulmonary embolus associated with Broviac catheterization in a 2-month-old. [37] Emergency department personnel should be vigilant for symptoms of pulmonary embolus and should inject fluids with care.

Catheter displacement may occur when patients do not remain still during the procedure. Harvey and colleagues [30] reported two cases of Hickman catheters being withdrawn accidentally by patients. Chardavoyne and coworkers [38] described a similar

case in which an implantable venous access device (Infuse-A-Port) spontaneously withdrew from the central circulation after documented placement. Care must be taken when handling both long-term venous access catheters and implantable venous access devices, especially in active patients.

## General Complications of Indwelling Lines and Arteriovenous Fistulas and Shunts

### Infectious complications.

Emergency department personnel must remain vigilant for catheter sepsis in immunocompromised patients with indwelling lines and fistulas. The long-term venous access catheter infection rate in adults is between 1.5 and 19%, [5] [11] [30] whereas implantable venous access device sepsis is less frequent at 3%. [11] Among children, 2.8 Hickman catheter infections occur for every 1000 catheter-days, [39] and children between 1 and 4 years of age have a greater risk of multiple septic complications. [39] Insertion site inflammation occurs in 26% of PICCs and 2.6% of short subclavian catheters, although wound site cultures are usually negative. [22] Changing a triple-lumen catheter every 3 days does not decrease the infection rate, and changing such catheters over guide wires increases the risk of bacteremia. [29]

Catheter infections occur at the skin exit site, SQ tunnel, and skin overlying the catheter (venous) insertion site. [30] The SQ tunnel and exit site seem to be involved more frequently. [30] Clinical manifestations include local erythema, tenderness, fever, and purulent drainage [5] ; however, generalized immune suppression may mask these signs. [30] Some authors identified acute leukemia as a risk factor for line sepsis, especially during neutropenia. [22] [30] However, Couch and associates [5] noted a lower infection rate and no such correlation when considering the total white blood cell count at the time of insertion into osteomyelitis patients.

Staphylococci, streptococci, and diphtheroid organisms are cultured most frequently from infected indwelling catheters (Table 25-2) . [14] [21] [33] [39] *Staphylococcus aureus* and *Staphylococcus epidermidis*[5] [14] [40] [41] are common, as are *Streptococcus faecalis, Streptococcus bovis,* and viridans group streptococci. [41] Group C streptococci have also been implicated. [42] Gram-negative bacteria occur less frequently and may be associated with a neutropenic state. [40] These organisms include *Pseudomonas aeruginosa, Klebsiella* spp., *Acinetobacter* spp., and *Serratia* spp.; *Corynebacterium* spp., [40] [43] *Bacillus* spp., [44] and atypical mycobacteria [45] [46] have also been implicated.

Fungal infections occur less frequently but are nonetheless virulent. Premature infants requiring prolonged hyperalimentation seem to be at greatest risk [47] [48] ; organisms cultured include *Candida* spp., *Malassezia pachydermatis,* and *Malassezia furfur,* the causative agent of tinea versicolor. [43] [47] [48] [49] [50] These children present with low-grade fever, bradycardia, thrombocytopenia, apnea, and a predominance of immature polymorphonucleocytes. [49] Adults may develop primary cutaneous aspergillosis near a long-term venous access catheter exit site, with erythema, induration, and black cutaneous necrosis. [51] One adult with acute nonlymphocytic leukemia presented with a mycotic aortic aneurysm while receiving outpatient

chemotherapy through a Hickman catheter. [49] Appropriate antifungal therapy includes ketoconazole, itraconazole, flucytosine, and amphotericin B on an inpatient basis. [49] [51]

Management of indwelling catheter infections must be coordinated through the patient's primary physician (e.g., hematologist, oncologist). After supportive measures have been undertaken, the primary considerations are (1) the choice of antimicrobial, (2) the decision to remove the indwelling line, and (3) the decision to hospitalize. Selected patients may not require catheter removal. [5] [43] [45] [52] Couch and associates [5] removed only 5 of 105 Hickman catheters from infected sites before completion of antimicrobial therapy. Furthermore, a portion of those treated without catheter removal may be followed as outpatients. [5] Criteria for outpatient management of indwelling catheter infections include

| TABLE 25-2 -- Microorganisms Causing Indwelling Catheter Infection | |
|---|---|
| **Bacterial** | |
| Gram-positive cocci | *Staphylococcus aureus, Staphylococcus epidermidis, Streptococcus faecalis, Streptococcus bovis,* group C streptococci, and viridans streptococcus |
| Gram-negative bacilli | *Pseudomonas aeruginosa, Klebsiella* sp., *Acinetobacter* sp., *Serratia* sp. |
| Gram-positive bacilli | *Bacillus cereus, Bacillus laterosporus, Corynebacterium* sp. |
| Atypical | *Mycobacterium neoaurum, Mycobacterium fortuitum, Mycobacterium chelonae* |
| **Mycotic** | *Malassezia furfur, Malassezia pachydermatis, Aspergillus fumigatus, Aspergillus flavus, Candida albicans* |

(1) a competent immune system; (2) an intelligent patient with adequate outpatient support; (3) an infection localized to the skin exit site; and (4) an absence of fever, leukocytosis, granulocytopenia, tachycardia, and hypotension.

Cultures are obtained of local purulent discharge, blood drawn through the catheter, and blood drawn from a distant site. An oral antimicrobial should then be chosen that covers both staphylococcal and streptococcal organisms; semisynthetic penicillins and first-generation cephalosporins are adequate. Finally, the patient may be released home only after consultation with the primary physician and assurance of 24- to 48-hour follow-up to ensure clinical reassessment and review of culture results.

All patients with indwelling catheter infections who fall outside of this narrow spectrum are hospitalized. Those who are hemodynamically stable may have cultures taken and be treated with IV antimicrobials that are effective against gram-positive and gram-negative organisms. Vancomycin is effective [21] [30] [53] because of its gram-positive spectrum and efficacy against diphtheroids, which may be resistant to other antimicrobials. Aminoglycosides provide adequate gram-negative coverage [53] ; however, broad-spectrum triple antimicrobial therapy may be necessary in neutropenic patients. Strong consideration should be given to catheter removal when hypotension supervenes. Before an indwelling line is removed, cultures of blood drawn through the device, as well as the catheter tip itself, should be obtained. The decision to remove a catheter should be made in concert with the consultant, as these devices are both surgically implanted and expensive. Local thrombolytic therapy may remove fibrin sheaths that entrap pyogenic bacteria near catheter tips and possibly obviate the need for catheter removal, especially in children.

Arteriovenous shunts are seen less frequently in the emergency department owing to the increased use of femoral and subclavian Uldall and Manhurkar catheters for temporary hemodialysis. Localized shunt infections are generally caused by staphylococci or streptococci. [54] Gram-negative organisms are implicated less frequently, and antimicrobial coverage may be extended to include them. [55] Arteriovenous fistula infections are rare but, when present, may lead to thrombosis and massive bleeding. [15] Overlying cellulitis without involvement of the fistula itself may be treated on an outpatient basis with a single IV dose of vancomycin followed by an oral antimicrobial (e.g., cephalexin). Involvement of the fistula itself mandates hospital admission and observation for hemorrhagic complications.

**Noninfectious complications.**

Catheter thrombosis occurs more frequently in long-term venous access catheters (22%) than in implantable venous access devices (1%), [11] and pulmonary embolism associated with indwelling lines has been reported. [30] [50] [56] Flushing these catheters with heparin, urokinase, and streptokinase should be done with great care and vigilance. One commonly used approach is to inject a 1-mL, 5000-unit dose of urokinase, allow it to dwell for 3 to 5 minutes, and then attempt to aspirate blood. If

unsuccessful, repeat the procedure. Before replacing the line, consider admission for a 12-hour continuous urokinase infusion. [57]

A potentially fatal pulmonary embolus may be heralded by the sudden onset of chest pain, shortness of breath, tachycardia, and tachypnea. Continuous urokinase therapy has been effective in resolving pulmonary emboli in the setting of a large right atrial thrombus. [37] Inability to clear an indwelling line using the measures described under Procedures necessitates peripheral venous access and referral for possible catheter replacement.

Fractures of Hickman-type catheters occur either subcutaneously or in the externalized portion. [58] SQ fractures cause localized pain and swelling, and the involved line should be removed, because complete fracture with embolization can occur, albeit rare. Embolization of a catheter fragment is life threatening and causes acute dyspnea, palpitations, atypical chest discomfort, hypoxia, and atrial fibrillation. Embolized fragments are localized by chest radiography and removed either surgically or nonsurgically. [59] [60]

Repair of fractures of externalized catheter portions is done using kits made by the appropriate manufacturer. In general, the catheter is cut proximal to the fracture, the damaged portion removed (discarded), a new catheter segment inserted into the proximal catheter segment, and an overlying sleeve glued to connect and seal the two segments together (Fig. 25-7) . The repaired catheter is then secured in place and cleared with standard flush solution. Gryn and Sacchetti recommend securing the repaired catheter to a tongue blade using tape several cm on each side of the splice sleeve. [58] Repairs of externalized catheter fractures within 2 cm of the insertion site represent a greater risk for failure and embolization. These repairs should be done by personnel familiar with such repairs. [58] When a repair kit is unavailable, temporary (emergency) vascular access can be achieved by transecting the leaking externalized catheter as above and then inserting an IV catheter (frequently a 14-ga catheter will suffice) into the exposed lumen.

Additional complications of indwelling lines include mediastinitis, cardiac dysrhythmias, superior vena cava syndrome, SQ tunnel hematoma, central vein stenosis, and septic atrial thrombosis associated with Budd-Chiari malformation. [5] [56] Erosion of the SQ tissue by the Dacron cuff, causing a superficial ulcer, also has been reported. [61] In addition, pneumothorax, cardiac tamponade, lymphatic duct puncture, air embolism, and brachial plexus injury may worsen among outpatients if the result of catheter insertion is not recognized immediately. [62]

**Figure 25-7** Catheter repair. A hollow lumen connector and outer sleeve are placed to splice a replacement catheter to the remaining catheter segment (see text).

The most life-threatening complication of arteriovenous fistulas is bleeding caused by either trauma or infection. Massive blood loss is possible because the arterial system is violated; treatment includes local pressure, IV access, oxygen, supportive therapy, and immediate vascular surgery referral to obtain definitive control of the bleeding site. If

bleeding is substantial and not easily controlled, consider IV protamine in a dose of 0.01 mg per unit of heparin, or 10 to 20 mg for 1000 to 2000 units of heparin. [63] If possible, consult with the patient's nephrologist or vascular surgeon before giving protamine.

In addition to hemorrhaging, arteriovenous fistulas may thrombose, a complication usually related to dehydration (e.g., after hemodialysis), hypotension, recent surgery, local trauma, or a superficial ulcer. [15] Recombinant human erythropoietin use is a risk factor for thrombosis. [64] Also, thromboses occur more frequently among graft fistulas than among endogenous grafts. [65] Patients with the loss of a bruit or thrill in a previously functioning shunt or fistula should be referred to a plastic surgeon for possible revision. Thrombectomy may salvage the fistula once these precipitating factors have been addressed. Alternative venous access for hemodialysis (e.g., Manhurkar catheter) may be necessary.

Shunt and fistula infections can be difficult to detect, because fever and leukocytosis are frequently absent. [66] If a shunt or fistula infection is suspected, the clinician should first culture the blood and infected site. Most febrile patients are admitted, although some are given an IV dose of antimicrobial and discharged with 24-hour follow-up. [63] Vancomycin is an effective choice for the most common pyogenic bacteria ( *Staphylococcus* spp.).

The steal syndrome occurs when blood passes preferentially through a low-resistance arteriovenous fistula at the expense of distal arteries. [67] It generally occurs within 24 hours of fistula surgery in 1 to 3% of patients. [68] [69] Symptoms include pain, paresthesia, and weakness of the fingers and hand. [15] Again, surgical evaluation of the fistula is indicated. Venous hypertension distal to a forearm fistula may lead to painful hand swelling, stasis changes, and hyperpigmentation. The fistula may need to be closed if symptoms persist. Finally, venous aneurysms commonly develop but are not life threatening if the overlying skin remains intact.

## CONCLUSION

Numerous methods of vascular access are currently available to the emergency physician, including indwelling catheters and arteriovenous anastomoses. Facility with these latter devices enables emergency department staff to access the venous circulation of a high-risk patient population in a relatively safe and painless manner. However, vigilance during these procedures is necessary to avert potentially life-threatening complications. Knowledge and recognition of these complications among outpatients may prevent sepsis and life-threatening hemorrhage.

# Chapter 26 - Intraosseous Infusion

**Frank J. Cunningham Jr., William H. Spivey**

Establishing vascular access in a critically ill or injured pediatric patient can be one of the most difficult and frustrating procedures a physician has to perform. For example, in a review of intravascular access in pediatric cardiac arrest, the mean (± SD) time needed to establish venous access was a disappointing 7.9 ± 4.2 minutes. [1] Although peripheral percutaneous venous access was the fastest method (mean time, 3.0 minutes), it was successful in only 17% of cases. Success rate was highest for an intraosseous (IO) infusion (83%), followed by surgical cutdown (81%), and central venous catheterization (77%). The mean time required to obtain a functioning IO line was 4.7 minutes, followed by 8.4 minutes for a central line, and 12.7 minutes for a cutdown. Another study of emergency department pediatric arrests demonstrated failure to gain intravenous (IV) access entirely in 6% of the patients. [2]

Small peripheral vessels in children often collapse during shock, and the child's increased body fat makes peripheral cannulation time consuming and at times impossible. Central venous cannulation can be equally difficult and carries the risk of pneumothorax or arterial injury. Alternative routes for drug administration, such as the endotracheal and rectal routes, do not provide rapid, reliable drug absorption during cardiac arrest. For example, epinephrine administered by the endotracheal route, although effective in a normally functioning cardiovascular system, is poorly absorbed and produces minimal physiologic response when administered during cardiac arrest. [3] [4]

In light of the need for rapid vascular access in pediatric patients, the previously abandoned technique of IO infusion has been reintroduced. It provides a safe, reliable method of accessing the cardiovascular system for administration of fluids and drugs during cardiac arrest and other resuscitations.

## BACKGROUND

One of the earliest references describing the IO route was by Drinker and colleagues, who in 1922 examined the circulation of the sternum and suggested it as a site for transfusion. [5] The route was not used clinically until 1934 when Josefson, a Swedish physician, administered liver concentrate into the sternum of 12 patients with pernicious anemia and reported that all 12 improved. [6] Subsequently, the technique became widespread in the Scandinavian countries.

In 1940 the technique was introduced to American physicians by Tocantins, who described a series of animal and clinical studies that demonstrated fluid was rapidly transported from the medullary cavity of long bones to the heart. [7] [8] [9] Over the next two decades, thousands of cases of IO infusion of blood, crystalloid substances, and drugs were reported. [10] [11] [12] Relatively few complications were reported, considering the needles were often left in place for 24 to 48 hours. Heinild and coworkers in 1947 reviewed 982 cases of IO infusion and reported only 18 failures and 5 cases of

osteomyelitis. [12] None of the cases of osteomyelitis occurred in patients who received isotonic solutions.

With the introduction of plastic catheters and improved cannulation skills, the need for IO infusion as an alternative route of access diminished, and the technique was all but abandoned. It was not until the mid-1980s that the technique was reintroduced in response to the need for immediate vascular access during cardiopulmonary resuscitation. [2] [13] Use of the technique during cardiac arrest was supported by experiments that demonstrated sodium bicarbonate was effectively transported to the heart during cardiac arrest. [14] Since then, the technique has become widespread throughout the United States and is recognized as an accepted alternative to IV access in pediatric emergencies. The safety, ease, and effectiveness of the technique have led to the extension of its use for out-of-hospital emergency care. [15] [16] [17] [18] There is renewed interest in its use in adults as well.

## ANATOMY AND PHYSIOLOGY

Long bones are richly vascular structures with a dynamic circulation that is capable of accepting large volumes of fluid and rapidly transporting fluids or drugs to the central circulation. The bone, like most organs, is supplied by a major artery (nutrient artery). The artery pierces the cortex and divides into ascending and descending branches, which further subdivide into arterioles that pierce the endosteal surface of the stratum compactum to become capillaries. The capillaries drain into medullary venous sinusoids throughout the medullary space that in turn drain into a central venous channel (Fig. 26-1) . The medullary sinusoids accept fluid and drugs during IO infusion and serve as a route for transport to the central venous channel, which exits the bone as nutrient and emissary veins. [20] The medullary cavity functions as a rigid, noncollapsable vein, even in the presence of profound shock or cardiopulmonary arrest. [21] Radiographic studies have demonstrated that radiopaque dye spreads only a few centimeters in the medullary space before being transported to the venous system. [22] The richly vascular red marrow cavity of the long bones is gradually replaced by less vascular yellow marrow after 5 years of age. [23]

Almost every drug and fluid commonly used in resuscitation

**Figure 26-1** Schematic diagram illustrating the venous drainage from the marrow of a long bone with an intraosseous (IO) needle in place.

has been reported in clinical and preclinical IO studies. Medications and fluids that have been administered through IO infusion are listed in Table 26-1 (Table Not Available) . Crystalloid infusion studies in animals have demonstrated that infusion rates of 10 to 17 mL/min may be achieved with gravity infusion and rates as high as 42 mL/min with a pressure infusion. [24] [25] [26] IO crystalloid infusion has been shown to produce a significant increase in blood pressure in a hemorrhagic shock model in rabbits. [27] In small animals (7 to 8 kg) the size of the marrow cavity is the rate-limiting factor, whereas in larger animals (12 to 15 kg), the size of the needle determines the flow. [26] Blood

under pressure can be infused approximately two thirds as fast as crystalloid fluids. [26]

Comparisons of IO and IV infusion of drugs have demonstrated that the drugs reach the central circulation by both routes in similar concentrations and at the same time (Fig. 26-2) . [7] [28] This holds true even during cardiopulmonary resuscitation (CPR), where sodium bicarbonate has been shown to provide a greater buffering capacity when administered by the IO route than by the peripheral IV route.

## INDICATIONS AND CONTRAINDICATIONS

IO infusion is a means of achieving rapid temporary vascular access until a patient can be stabilized and traditional IV access obtained. It is indicated when fluid or drugs must be introduced into the circulation rapidly and venous access is not readily available. The primary indication is cardiac arrest in an infant or child. The route has been used in adults, [29] but vascular access is usually easily obtainable, and alternatives to IV access are not often needed. In pediatric patients it may be used as a first line of vascular access if peripheral vascular access does not appear to be readily obtainable. Other indications include shock, trauma, extensive burns, severe dehydration, and status epilepticus, or any situation in which the emergency administration of fluids or drugs is necessary but not feasible by other routes. [30] IO infusion into the tibia also has been used as a site for lower extremity venography. [31]

In addition to serving as a route for fluid administration, the IO needle may be used for obtaining blood for type, crossmatch, and blood chemistry determinations from the marrow cavity. Serum electrolyte, blood urea nitrogen (BUN), creatinine, glucose, and calcium levels are very similar to those in samples obtained from an IO aspirate. [32] [33] Blood gas values obtained from the IO site also are similar to those

**Figure 26-2** Serum diazepam levels (ng/mL, mean ± SE) graphed for the IO *(shaded area)* and intravenous (IV) *(blackened area)* groups as a function of time when injected during normal perfusion. Initially the IV drug level is slightly higher, but overall the difference between the two routes of administration is not significant.

obtained from central venous sites during steady- and low-flow states in one animal model and may be an acceptable alternative to judging central acid-base status during CPR. [34] A complete blood cell count may not be reliable, because it reflects the marrow cell count rather than the cell count in the peripheral circulation. Furthermore, the aspirated blood usually clots within seconds, even if it is placed in a tube that contains heparin. Brickman and colleagues demonstrated that bone marrow aspirates obtained from an IO needle in the iliac crest could be reliably used to type and screen blood for transfusion. [35]

Relatively few contraindications to IO infusion exist. Osteoporosis and osteogenesis imperfecta are associated with a high fracture potential; the procedure should be avoided when these diagnoses are known. A fractured bone must be avoided, because as fluid is infused, it increases the intramedullary pressure and forces fluid to extravasate at the fracture site. This may slow the healing process, cause a nonunion of

the bone, or lead to a compartment syndrome. A similar extravasation of fluid can occur through recent IO puncture sites placed in the same bone. Hence, recent prior use of the same bone for IO infusion represents a relative contraindication to IO line placement. Areas of cellulitis or infection or burns at or near the intended insertion site should be avoided if possible.

## EQUIPMENT AND SETUP

The only equipment necessary for establishing IO access is a sturdy needle with a stylet and a syringe for aspiration. Needles range in size from 20 to 13 ga and are made by several companies. Standard needles for drawing blood or administering medications are *not adequate* for IO infusions; they generally are not sturdy enough to penetrate bone. A cadaver study of IO puncture suggests that non-styletted needles (2.5 cm, 18-ga phlebotomy needles and 7.6 cm, 14-ga IV needles) enter the marrow space successfully about half the time. [36] In the past, an 18-ga spinal needle was commonly used for children younger than 12 to 18 months of age. This needle, although readily available in most emergency departments, often bends and is too long for rapid fluid infusion.

Several needles are currently used in emergency departments for IO infusion (Fig. 26-3) . Bone marrow aspiration needles such as the Rosenthal or Osgood can be used if available. They are large enough (16 ga) to be used on older children or adults and are good for fluid administration. The Illinois sternal/iliac aspiration needle (Monoject, Division of Sherwood Medical, St. Louis) is a 16-ga needle that has an adjustable plastic sleeve to prevent the needle from penetrating too deeply or through the opposite cortex. Its disadvantage is that it has a long shaft and cumbersome handle that make it vulnerable to dislodgment from the bone during transport or other procedures. The Cook IO needle (Cook Critical Care, Bloomington, Ind) comes in 18- and 16-ga sizes and has a detachable handle that decreases the likelihood of its being dislodged. A useful feature of this needle is a line located 1 cm from the tip of the needle to serve as a depth marker. The Sur-Fast needle (Cook Critical Care, Inc., Bloomington, Ind) has a threaded shaft to permit a more secure needle placement. The Jamshidi Disposable Illinois sternal/iliac aspiration needle (Baxter Healthcare, Valencia,

**Figure 26-3** Needles used for intraosseous infusion. *Left to right,* MedSurg Industries bone marrow aspiration needle, MedSurg Industries Illinois sternal/iliac aspiration needle, Jamshidi disposable sternal/iliac aspiration needle, Cook IO needle with 45° trocar, Sur-Fast IO needle.

Calif) comes in either 15- or 18-ga sizes and, like the larger Illinois sternal/iliac aspiration needle mentioned above, features an adjustable plastic sleeve. However, its shorter shaft length and smaller handle make it much easier to use. A 13-ga needle manufactured by MedSurg Industries (Rockville, Md) is good for fluid resuscitation. However, like the Illinois sternal/iliac aspiration needle, this latter product has a large handle that makes it cumbersome.

## TECHNIQUE

Originally the sternum was used as a site for IO infusion. After several cases of osteomyelitis and mediastinitis in children, the site was abandoned. [37] Other sites, such as the clavicle and humerus, have been used, but neither has gained popularity. Currently the site of choice is the proximal tibia, followed by the distal tibia and distal femur.

The tibia is popular because it is a large bone with a thin layer of subcutaneous tissue that allows landmarks to be readily palpated. It is the preferred site of IO insertion in infants and children <6 years of age, and its insertion does not interfere with airway management and cardiopulmonary resuscitation. On the proximal tibia, the broad, flat anteromedial surface is used, with the tibial tuberosity serving as a landmark. The site of IO cannulation is approximately 1 to 3 cm (2 fingerwidths) below the tuberosity on the medial or flat surface of the tibia (Fig. 26-4 *A*). This location is far enough from the growth plate to prevent damage but is in an area in which the bone is still soft enough to allow easy penetration of a needle. This site may be used in adults but is more difficult and requires a 16- to 13-ga needle to penetrate.

The patient's leg should be supported by placing a small sandbag or towel roll behind the knee. The site is prepared with a povidone-iodine solution or alcohol. Local anesthesia is usually unnecessary, since the majority of patients in whom IO is used have altered mental status from shock or are in cardiopulmonary arrest. However, if the patient is conscious, the skin and periosteum should be anesthetized. The thigh and knee above and lateral to the insertion site are grasped with the palm of the nondominant hand (Fig. 26-5) . The fingers and thumb are wrapped around the knee to stabilize the proximal tibia. To avoid self-puncture, care must be taken to ensure that the hand does not extend behind the insertion site.

The bony landmarks are palpated and the site identified. The needle should be grasped firmly in the palm of the hand and is directed either perpendicular (90°) to the long axis of the bone or slightly caudad (60° to 75°) to avoid penetration or injury to the growth plate. The needle is then advanced with a twisting or rotary motion to cut the bone and facilitate puncture of the cortex. Considerable resistance will be encountered, but once the cortex has been penetrated, there is a sudden decrease in resistance and a crunching feeling as the needle moves through the bony trabeculae into the marrow cavity. The distance from the skin through the cortex of the bone is rarely >1 cm in an infant or child, and penetration to this depth is usually adequate. A common mistake is to advance the needle through the opposite side of the bone. This can best be avoided by holding the needle in the palm of the hand with the index finger approximately 1 cm from the bevel of the needle to avoid pushing it past this mark. Another method is to use a needle with a preset plastic depth indicator on the shaft. [38] The stylet is then removed, and a 5- to 10-mL syringe is used to aspirate blood and marrow contents for confirmation of position. Many times, particularly during cardiac arrest, blood aspiration is not possible. Other signs of successful needle insertion include the needle's ability to stand upright without support and infused fluids that flow easily without evidence of swelling or extravasation.

If there is excessive resistance to fluid infusion, the needle may be pulled back a few

millimeters and another attempt made to infuse fluids. If continued resistance is met or evidence of extravasation exists, the needle should be removed and an attempt made on the other extremity. If the needle appears to be infusing properly, the test syringe is disconnected, and the needle is then connected to infusion tubing. The needle and tubing should be secured with tape and the extremity immobilized on a leg board (Fig. 26-6 A). The needle should be protected from accidental dislodgment by wrapping a stretch bandage around the extremity and placing a small plastic drinking cup around the needle (Fig. 26-6 B). The IO needle should be removed as soon as secure IV access has been obtained. A sterile dressing is placed over the puncture site, and pressure should be applied to the dressing for 5 minutes. [39]

The distal tibia, although the preferred site in adults, may be used as well in children. [29] [40] The cortex of the bone and the overlying tissue are both thin. The site of needle insertion is the medial surface at the junction of the medial malleolus and the shaft of the tibia, posterior to the greater saphenous vein (see Fig. 26-4 B). The needle is inserted perpendicular to the long axis of the bone or 10° to 15° cephalad to avoid the growth plate. [38]

The distal portion of the femur is occasionally used as an alternate site, but because of thick overlying muscle and soft tissue, it is more difficult to palpate bony landmarks (Fig. 26-4 C). If chosen, the needle should be inserted 2 to 3 cm above the external femoral condyles in the midline and directed cephalad at an angle of 10° to 15° from the vertical. [41]

In one study, similar rapid central circulation times of medications were noted when the distal tibia, proximal tibia, distal femur, and proximal humerus were compared to a peripheral IV site in a swine model, suggesting that adjustments in drug dosage may not be required for intraosseously administered medications

## COMPLICATIONS

As with any procedure, complications may arise when attempting to use the bone for vascular access. Complications may be divided into two categories: technical difficulties and latent soft tissue or bone problems. Technical difficulties are the most common, but these decrease as familiarity with the technique increases (Fig. 26-7) . The most common mistake is to place excessive pressure on the needle during insertion and force it through the bone (Fig. 26-8) . This may be avoided by placing the index finger against the skin to prevent the needle from going in too deeply. Also, attention to depth of the needle or use of a sheath on the needle to prevent excess penetration will decrease occurrences of this problem. Incomplete penetration of the bone may also occur, in which case blood will not be aspirated and fluid will extravasate if infused. Serum levels of medication are decreased when IO infusion is performed through bones with multiple cortical defects. [43] If several attempts are made to place a needle in the same bone, fluid may extravasate from previous puncture wounds. If extravasation occurs, the needle should be removed and pressure applied.

The needle may be blocked periodically by clots forming around the bevel or by bony spicules obstructing the flow of fluid. This complication may require that the line be

flushed with 3 to 5 mL of sterile saline every 10 to 15 minutes to keep it open. Pressure infusions usually do not require taking this step.

A major concern for any person receiving IO infusion is infection. This concern often leads physicians to shy away from using the bone and to continue searching for other methods of vascular access. Although the potential for infection is real, its actual incidence is low. A literature review of more than 4000 cases from 1942 to 1977 found a 0.6% incidence of infection. [2] Although most of the affected access sites were not placed under emergency conditions, the needles were often left in 1 to 2 days, thus increasing the likelihood of infection. A survey of more than 1000 U.S. and foreign medical schools found that the incidence of infection for IO needles placed in emergency conditions was <3%. [44]

The most common infection is cellulitis at the puncture site, which usually responds well to antibiotics. Osteomyelitis is less common, but it also usually responds to antibiotics. Heinild and colleagues reported three cases of osteomyelitis in 25 patients who received infusions of undiluted 50% dextrose in water ($D_{50}W$). [12] Undiluted $D_{50}W$ injected into rabbit femurs produces edema and pyknotic marrow nuclei that improve within 1 month. [45] In addition to infection, inflammatory reactions of the bone may be seen. These are most common when hypertonic or sclerosing agents are used and may produce an elevation of the periosteum with a positive bone scan (Fig. 26-9) . Unlike the clinical appearance of a patient with osteomyelitis due to bacteria, a child with a sterile inflammatory reaction does not look "toxic." One hypertonic sclerosing drug that is routinely used during cardiac arrest is sodium bicarbonate. Heinild and coworkers reported 78 cases of bicarbonate infusion with no complications. [12] Animal studies have reported a decrease in cellularity with edema and destruction of some cells, but these changes are temporary and completely resolve in a few weeks. [45] [46] [47]

Another complication that has been reported is necrosis and sloughing of the skin at the site of infusion. [48] This occurs if fluid or drugs extravasate from the puncture site into the surrounding tissues. Care should be taken when infusing drugs such as calcium chloride, epinephrine, and sodium bicarbonate to prevent dislodgment of the needle and extravasation into the tissue. It is best to infuse such drugs gently and not under pressure, because pressure frequently causes extravasation.

Injury of the growth plate and developmental abnormalities of the bone are ongoing concerns. These fears have not been supported in the literature, however. There have been no reports of growth plate damage or permanent abnormalities of the bone. One animal study specifically examined damage to the epiphysis; sodium bicarbonate was injected directly into the epiphysis, and no radiologic evidence of epiphyseal injury was found. [49] [50] By pointing the needle away from the joint space and using the previously mentioned landmarks for insertion, the danger of epiphyseal injury is remote.

Fat embolism is frequently mentioned as a potential complication. [2] [40] However, this condition is rare and has been reported only in adult patients. [51] Animal studies addressing this issue found no changes in blood gases during IO infusion and limited evidence of fat globule collection in the lungs. [52] [53] Because the marrow in infants and children is primarily hematopoietic, this potential complication is unlikely to occur. In one

animal study, no significant hemolysis was detected in the setting of pressurized IO blood infusion. [52]

Compartment syndrome following IO line use during cardiac resuscitation has been reported. [54] [55] Tibial fractures have also been reported. [56] [57] Follow-up radiographs of patients who have undergone IO needle placement or attempts at such placement are indicated. Cortical defects may be seen on radiographs for up to 40 days after injection.

## INTERPRETATION

The determination of whether an IO infusion is functioning may be made by assessing the ease with which fluid infuses and the clinical response of the patient. If the needle is properly placed, fluid should flow smoothly, with only occasional flushes necessary to keep it open. A clinical response to fluid or medications should be seen at approximately the same time and in the same magnitude as with IV administration.

## CONCLUSION

IO infusion provides a means of rapidly accessing the cardiovascular system in emergencies. The technique is not intended to replace traditional venous access; instead it should serve as a temporizing measure for resuscitation until venous access can be obtained. It is currently used widely throughout the United States and Canada and has been reviewed extensively in the emergency medicine and pediatric literature. The technique also is used by out-of-hospital emergency care personnel, who have demonstrated a high success rate in the field. [17] [59] The technique renders hope for those who infrequently care for critically ill or injured children, because this skill is easily mastered even if done infrequently.

Complications are most commonly related to technical mistakes. By carefully locating landmarks, staying away from the growth plate, and paying attention to the depth of the needle, complications can be minimized. Finally, as with any technique, practice on cadaver or animal leg bones (e.g., chicken, pig) greatly improves one's skill.

# Chapter 27 - Endotracheal Drug Administration

**James H. Bryan** , **J. Thomas Ward Jr.**

Endotracheal (ET) administration of selected medications is a simple, rapid, and effective method of drug delivery to the central circulation. However, this technique of drug administration should be reserved for use in situations in which a patient's condition warrants immediate pharmacologic intervention and when more conventional means of drug delivery, such as by intravenous (IV) or intraosseous (IO) access, are not readily available. Such circumstances occur infrequently, but when they do occur, knowledge of the appropriate drugs and dosages that can be delivered effectively by this route may prove to be life saving. It is important, therefore, that physicians be familiar with the concept and method of ET drug therapy.

Endotracheal drug administration dates to 1857, when Bernard demonstrated the ability of the lung to rapidly absorb an instilled solution of curare. [1] In this experiment, curare was instilled into the upper respiratory tract of dogs by way of a tracheostomy. After the dogs were tilted to an upright position, they died within 7 to 8 minutes. Bernard concluded that the alveoli must be permeable to curare. Over the following decades, other investigators expanded this work and demonstrated that solutions containing salicylates, atropine, potassium iodide, strychnine, and chloral hydrate were also absorbed rapidly from the lung and excreted

in the urine after injection of their aqueous solutions into the tracheas of experimental animals. [2]

In 1915, Kline and Winternitz provided experimental data suggesting that intratracheal therapy in pulmonary disease might prove to be an effective therapeutic route. [3] Further studies showed that moderate quantities of fluid could be insufflated into the lungs without marked changes in the lung architecture. [4] The use of intrapulmonary medication in the treatment of lung disease gained further acceptance when studies demonstrated that the inhalation of epinephrine mist dramatically relieved the symptoms of asthma. [5]

In the late 1930s and 1940s when certain chronic suppurative disorders of the lung failed to respond to parenteral antibiotics, drugs were administered by direct instillation into the lungs. During this period, several important observations were made concerning ET drug therapy: (1) penicillin delivered by the ET route demonstrated a depot effect, resulting in therapeutic blood levels that lasted twice as long as those noted with intramuscular injections [6] ; (2) various diluents mixed with penicillin affected both the rate and the degree of absorption from the lungs [7] ; and (3) higher serum drug levels were attained with direct ET drug administration than with aerosolized administration. [7]

In the 1950s, other important findings concerning the ET administration of drugs were established by investigators attempting to elucidate the mechanism responsible for adverse anesthetic reactions. This research demonstrated two important points. First, drugs delivered endotracheally were absorbed much more rapidly than those applied to

the posterior pharynx. Second, the rapid absorption of drugs applied locally to the larynx and trachea resulted in blood levels significant enough to cause adverse anesthetic reactions. [8]

In 1967, Redding and coworkers studied the use of ET administration as a route of drug delivery in a canine model of cardiopulmonary arrest. [9] They administered epinephrine by the IV, intracardiac, and intratracheal routes, and then evaluated its effectiveness in the resuscitation of dogs that had undergone both respiratory and circulatory arrest secondary to hypoxia. Their study revealed that all three routes of drug administration were equally effective in restoring the circulation of dogs in *hypoxia-induced* cardiac arrest, again demonstrating that the ET route of drug delivery provides an effective window to the systemic circulation. They concluded that whichever of these routes is most immediately available should be used.

A decade passed before further research was published concerning the use of ET drug therapy as an alternative means of systemic drug administration. In the late 1970s, Roberts and Greenberg and associates revived the study of ET drug delivery with a series of laboratory experiments and clinical uses of ET epinephrine. [10] [11] [12] [13] Since that time, a number of important animal and human studies, as well as a number of case reports, have been published dealing with various aspects of ET drug administration. These investigations have addressed (1) the appropriate dose of drug to administer; (2) the effect of drug solution volume; (3) the effect of different diluent solutions; (4) the role of different ET drug delivery techniques; and (5) the effects of hypoxia, hypotension, shock, and cardiopulmonary arrest on the absorption, distribution, and efficacy of endotracheally administered drugs.

## RECOMMENDATIONS REGARDING ENDOTRACHEAL DRUG DELIVERY

Although the American Heart Association's (AHA) Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiac Care make specific recommendations regarding the use of ET drug delivery for cardiac resuscitation (Table 27-1) (Table Not Available) , [14] [15] [16] much of the literature remains controversial and is at times contradictory. It is likely, therefore, that many of these issues will continue to be the subject of future investigations. Specific studies related to each of these topics are discussed in the following paragraphs.

### Appropriate Dose

All investigators agree that the ET dose of a medication should be at least equal to the IV dose of the same drug given for the same indication. Most studies on the subject indicate that higher doses are needed endotracheally than intravenously. For Advanced Cardiac Life Support medications in adults, the AHA recommends a dose 2.0 to 2.5 times the usual IV dose. [14] This recommendation is supported by the results of a study of epinephrine administered immediately following intubation in the out-of-hospital setting. [17] There are, however, other studies that suggest that ET administration

requires higher doses.

In studies of endotracheally administered lidocaine, a 3 mg/kg dose was needed to obtain therapeutic serum levels. Studies and case reports of ET epinephrine have produced conflicting results. Some animal studies [20] and case reports [13] have shown positive effects and/or recovery from cardiovascular collapse when epinephrine was used in doses equal to recommended IV doses. In other animal [21] and human [22] studies, however, epinephrine in doses of approximately 0.02 mg/kg and 0.01 mg/kg, respectively, were shown to be unreliable in producing a physiologic response. In addition, studies using both normotensive and cardiac arrest canine models have shown that epinephrine doses of 0.01 mg/kg produce serum levels approximately one-tenth that produced when the same dose is given IV. [11] [23] [24] These studies recommend increasing the ET epinephrine dose to 0.1 mg/kg and are the basis for the AHA recommendation to use a 10-fold increased dose when administering ET epinephrine to pediatric patients. [15] However, ET drug delivery is associated with a depot effect. That is, when larger doses of drugs are administered via the ET route, the drug is "stored" and released slowly over time, similar to a continuous IV drip. This presumably occurs due to local vasoconstriction and/or lymphatic storage of the drug. [10] With epinephrine use, the depot effect produces a potential for postresuscitative arrhythmias, hypertension, and tachycardia, with resultant increased myocardial oxygen demand.

Given these data, it seems reasonable in adults to start with a dose 2.0 to 2.5 times the usual IV dose. If this appears ineffective, higher doses may be used on subsequent administration.

**Single-Dose Volume**

The need to increase the volume of the instilled medication to enhance effectiveness was recognized by Redding and associates during their early studies. [9] The goal is to use a volume that will enhance delivery and absorption of the drug while at the same time producing minimal deleterious effects on pulmonary gas exchange. The AHA recommends a total volume of 10 mL in adults [14] and 1-2 mL in pediatric patients and neonates. [15] [16] In studies with dogs, Mace compared undiluted lidocaine to diluted lidocaine (volume, 6.5 mL) and found significantly higher plasma lidocaine levels in the animals receiving diluted lidocaine. [25] There were no changes in the arterial blood gas values before and after ET drug administration. In another animal study, lidocaine diluted with normal saline to volumes up to 25 mL produced no changes in arterial blood gases or clinical condition, and no change was seen in lung gross anatomy or histology. [26] In contrast, a study comparing normal saline to distilled water revealed a decreased $Pa_{O2}$ for both solutions (water producing the greatest effect), but this study used large volumes (2 mL/kg) of solution. [27]

Studies of endotracheally administered lidocaine in human subjects revealed that dilution with distilled water to a total volume of 10 mL resulted in higher plasma lidocaine levels, but also produced a decrease in $Pa_{O2}$ of approximately 40 mm Hg that persisted for more than 1 hour. [28] A total volume of 5 mL yielded lower plasma levels but also produced a shorter period of hypoxemia. The authors concluded that a total volume of 5 to 10 mL (in agreement with the AHA guidelines) would produce optimal results. Volume

recommendations in the setting in which multiple doses of drug may be given (e.g., out-of-hospital arrest without peripheral venous access in a patient who may be facing long transport) are lacking. In this setting it may be appropriate to limit the diluent volume for an individual adult administration to 5 mL.

**Appropriate Diluent**

Due to their availability during emergency situations, both normal saline and distilled water have historically been the diluents of choice for ET drug administration. The AHA Adult Advanced Cardiac Life Support Guidelines recommend either diluent, noting that "endotracheal absorption is greater with distilled water than with normal saline, but distilled water has a more negative effect on Pa$_{O2}$ ." [14]

The use of saline is supported by the canine study of Greenberg and associates, which reported that administration of normal saline via the ET route produced fewer detrimental effects on arterial blood gases than did distilled water. [27] The safety of endotracheally administered normal saline is further supported by a study in which no changes in pulmonary status (arterial blood gas, oxygen saturation, gross anatomy, or histology) were observed in dogs given lidocaine diluted with normal saline to total volumes of between 6 and 25 mL. [26] In contrast, Hahnel and colleagues studied absorption of lidocaine when administered endotracheally in either normal saline or distilled water and found that saline impaired Pa$_{O2}$ more than distilled water. [29] In addition, they reported higher serum levels when lidocaine was diluted with distilled water. They concluded that distilled water is probably a better diluent than normal saline. Finally, a study of ET epinephrine diluted with either normal saline or distilled water found no difference in arterial blood gases between either the solution or the control. [30] In this latter canine cardiac arrest model, survival rates for ET epinephrine in either diluent were equal to the rate with IV epinephrine. Hence, the optimal diluent is controversial; saline and distilled water both can produce pulmonary dysfunction when administered in excess.

**Technique for Endotracheal Drug Delivery**

Multiple techniques have been used to deliver medications via the ET tube, including direct instillation into the proximal end of the ET tube, ET administration via a catheter that extends just beyond the distal tip of the ET tube, deep endobronchial administration using a longer catheter, administration via ET tube monitoring ports, and injection through the side of the ET tube with a needle. The AHA Advanced Cardiac Life Support Guidelines for adults and children and the Neonatal Resuscitation Guidelines recommend the use of a catheter that extends beyond the distal tip of the ET tube to minimize drug adherence to the ET tube and to enhance alveolar delivery. [14] [15] [16] However, several studies have indicated that this practice may not be necessary.

Greenberg and Spivey instilled radiopaque contrast material directly into the proximal end of the ET tube and compared its distribution to contrast instilled via a catheter extending out the distal end of the tube. [30A] Their study revealed that both techniques were equally effective in distributing

the contrast agent to the peripheral lung fields as long as instillation was followed by five rapid manual hyperventilations. Although some studies have suggested that drug absorption with direct instillation into the ET tube is inconsistent during cardiopulmonary arrest, [19] [22] at least one case report has shown successful resuscitation using this method. [13] In addition, using a porcine cardiopulmonary arrest model, Jasani and coworkers showed no difference in resuscitation rates or physiologic responses between epinephrine administered by direct injection into the ET tube, via a catheter extending out the distal end of the ET tube, or via a monitoring lumen built into the sidewall of the ET tube. [31] In a related study, no difference was detected in resuscitation rates or plasma epinephrine levels when epinephrine was instilled during apnea vs instillation during the ventilator inspiratory cycle. [32]

However, in studies in which subjects had normal perfusion, conflicting results have been reported. In one study using female volunteers, no difference was found in plasma lidocaine levels when the drug was administered directly into the proximal end of the ET tube vs deeper administration into the trachea or lungs. [33] However, a later report by the same group demonstrated significantly higher plasma lidocaine concentrations when the drug was administered directly into the proximal end of the ET tube. [34] In direct contrast, when administered to dogs, significantly higher plasma epinephrine levels were obtained via the deep endobronchial route vs direct ET tube instillation. [35]

Given these conflicting studies, use of a catheter to enhance deep pulmonary delivery seems reasonable. However, if a catheter is not readily available, alternative routes appear justified.

**Effects of Hypoxia, Hypotension, and Cardiopulmonary Arrest**

Several authors have examined the effect of cardiopulmonary arrest on the absorption of medications administered via the ET route. Although concern existed that medication absorption might decrease in states of hypoxia or low blood flow, studies reveal the opposite to be true. In a hemorrhagic shock model, Mace demonstrated that higher plasma lidocaine levels were obtained via the ET route during shock than during nonshock states. [36] In a lamb model, when epinephrine was administered endotracheally, higher plasma epinephrine levels were achieved during hypoxia-induced low pulmonary blood flow than during baseline, normal pulmonary blood flow. [37] Finally, higher plasma lidocaine levels were initially observed when lidocaine was administered endotracheally to dogs with hypoxemia than to dogs that were not hypoxemic. [38] However, this study did not find a difference in the pharmacokinetics of lidocaine in hypoxemic and nonhypoxemic dogs when the drug was administered via the ET route.

Despite evidence indicating that cardiopulmonary arrest does not inhibit absorption of endotracheally administered medications, other studies have indicated that ET drugs are unreliable during cardiopulmonary arrest. [19] [21] [22] The latter studies serve to emphasize that ET drug administration should not be used in lieu of attempts to obtain definitive access to the systemic circulation. Therefore, ET drug administration should not be performed when another more direct means of accessing the central circulation

is available.

* See text--effective, but produced pneumonitis in one animal model.

## INDICATIONS

Endotracheal drug therapy is indicated whenever there is a need for emergent pharmacologic intervention and other access, either IV or IO, is not readily available. This most frequently occurs in patients with poor veins (e.g., patients receiving chemotherapy, dialysis patients, drug abusers, elderly patients), in patients with small or obscured veins (e.g., pediatric patients, burn patients, obese patients), or during cardiovascular collapse (e.g., cardiac or traumatic arrest).

Specific indications for the delivery of a drug endotracheally are the same as those for IV and IO administration. However, there are only a limited number of emergency drugs that can be given safely and effectively by the ET route (Tables 27-2 and 27-3) . Medications that have been administered endotracheally and found to be safe and effective in both experimental animal models and human studies or case reports include epinephrine,  atropine,  lidocaine, and naloxone.

Diazepam also has been shown to be effective. [46] [47] However, in one animal model, diazepam produced pneumonitis when 0.5 mg/kg was administered via the ET route. [48] Because diazepam is sparingly soluble in water, it is available only in a solution of

propylene glycol, ethanol, and benzyl alcohol. It is unknown if the reported pneumonitis was due to the direct effects of the diazepam or to that of the diluent.

In one case report, 5 mg of diazepam (i.e., approximately 0.1 mg/kg) was administered via a tracheostomy to an adult female, resulting in cessation of seizure activity within 2 minutes. [47] In this report, no change in arterial blood gas values or chest x-rays was noted over the ensuing 5 days. Whether the apparent lack of adverse pulmonary effects in this patient implies that diazepam can be safely used via the ET route is still speculative. The lower dose used (0.1 mg/kg) may have been a factor in reducing pulmonary damage. A further issue, given the low solubility of diazepam in water, is the ability to dilute stock diazepam solutions to a total volume of 10 mL (as is recommended for ET drug administration). A volume of 10 mL of propylene glycol or ethanol used as diluent may further compromise pulmonary function. Additional studies are needed to resolve these issues, but some authors have removed diazepam from their

|---|
| Midazolam |
| Metaraminol |
| Propranolol |

list of medications that can be given safely via the ET route. [49] [50]

Experimental studies of midazolam, [51] propranolol, [41] and metaraminol [52] in animal models suggest that these medications also may be effective when administered endotracheally, but no clinical studies have been conducted to date to verify these findings. It is of interest to note that in the study of midazolam, no pathologic changes were seen in lung sections after midazolam administration. [51] In addition, midazolam is available commercially in aqueous solution and can, therefore, be diluted with normal saline or sterile water for ET administration. Although clinical studies are needed for confirmation, midazolam may prove to be a viable alternative to diazepam when IV or IO access is not obtainable.

## CONTRAINDICATIONS

At present, the only true contraindication to the ET delivery of an appropriate drug is the presence of another form of access to the systemic circulation through which the needed drug can be delivered rapidly and effectively. The pharmacokinetics and pharmacodynamics of ET drugs delivered during various states of cardiovascular or pulmonary compromise are to a large extent unknown, and for that reason, more conventional routes of rapid and effective drug administration should be used when available.

No drug should be delivered by the ET route without experimental or clinical evidence to support its effectiveness and safety. A complete list of drugs that are contraindicated relative to delivery by the ET method is not available. Specific emergency medications that have been shown to be ineffective or unsafe when given via the ET route include sodium bicarbonate, isoproterenol, and bretylium. In a study using a canine model, sodium bicarbonate was shown to inactivate lung surfactant. [53] Isoproterenol, even when given in doses ten times the IV dose, failed to produce significant changes in arterial blood pressure or heart rate. [41] Studies of bretylium also indicate low serum levels after ET administration, even when administered at doses of 20 mg/kg.

## EQUIPMENT

Patients in need of ET drug therapy first require management of the airway, usually in the form of tracheal intubation. Once this procedure has been performed (see Chapter 2) , little other equipment is needed for the ET delivery of a drug. In the Procedure section that follows, several different techniques for ET drug administration are described. The equipment listed below is that required to perform any of the four different techniques described. This equipment is suggested for the ideal situation and/or technique. *At no time should drug delivery be delayed while searching for the "perfect" piece of equipment.*

1. Manual bag-valve ventilation device capable of delivering an $F_{IO_2}$ of at least 50%. In circumstances in which ET drug delivery is indicated, the patient's condition almost always warrants supplemental oxygen. Although the technique may not result in any significant deterioration in respiratory function, it is still advisable to administer additional oxygen after drug delivery. The bag-valve ventilation device also is used to deliver several rapid insufflations immediately after drug delivery to assist delivery of the drug distally, where it may be absorbed more rapidly and effectively. [30A]
2. A fine-bore catheter or special ET tube to deliver the drug at or beyond the distal end of the ET tube. The ideal catheter is at least 8 Fr in size and at least 35 cm (14 in.) in length. The most effective length or diameter of the catheter is unknown, but it is recommended that the catheter be long enough to protrude past the distal end of the ET tube. The diameter of the catheter should be large enough to allow rapid delivery of a 10 mL volume of solution. Several different types of tubes and catheters commonly available in the emergency department can be used for this

purpose:

A 16-ga central venous pressure or cutdown catheter. Most of these are only 30 cm in length, however, and the proximal end of the ET tube requires shortening if the catheter is to protrude past the distal end of the ET tube.

An 8 or 10 Fr polyethylene pediatric feeding tube (e.g., Argle, St. Louis). These tubes are much longer than needed and should be cut to the desired length to reduce dead space. Luer-Lok-type syringes and IV adapter locks both fit nicely onto the proximal end of the tube.

An 8 Fr (or larger) pediatric pulmonary suction catheter without the control port. Because this catheter is designed to extend past the tip of the ET tube, it is an ideal length. However, with some brands, it is difficult to attach a syringe or IV adapter lock after the suction control port is removed.

Alternatively, two ET tubes with built-in ports are available that allow ET instillation of drugs without removing the bag ventilation device. Unless these special tubes are used for all patients requiring intubation, the major drawback is the obvious need to decide prior to intubation if IV access is expected to be a problem. In these cases, the patient can be intubated using one of these tubes in anticipation of the need for ET drug administration. The available tubes include the following:

Endotracheal tubes designed for bronchoscopy (e.g., Hi-Lo Jet Tracheal Tube, Mallinckrodt Medical, St. Louis). These tubes have two additional ports, one used for monitoring or irrigation (opaque lumen) and one used for jet ventilation (transparent lumen). They are available in adult and pediatric sizes (cuffed and uncuffed). In a porcine cardiopulmonary arrest model, successful resuscitation using this tube was comparable to resuscitation using other forms of ET drug administration. [31] The major disadvantage to this ET tube is the need to be familiar with the specific ports prior to use. Determining which is the irrigation port if one has never seen the tube previously could prove to be time consuming. In addition, the port requires placement of an IV adapter lock to use prefilled syringes (in which most emergency medications are now supplied).

The EMT tracheal tube (Mallinckrodt Medical, St. Louis). This tube is designed specifically for ET drug administration. The instillation lumen opens into the tube at the eye, approximately 1 cm from the end of the tube. The injection port has an IV adapter lock, which makes it amenable to use with prefilled syringes.

The EMT tube is not available in pediatric sizes, and although its design is theoretically sound, no studies have been completed at this time that demonstrate an advantage over ET drug delivery using other techniques with standard ET tubes.

1. An IV adapter lock. This can be placed as needed onto the proximal end of the ET tube or catheters described previously to convert them for use with prefilled

syringes. This adapter is usually unnecessary if a standard syringe is used.
2. A 10 to 20 mL syringe, preferably a Luer-Lok type, big enough to deliver the desired volume of drug solution plus an additional 5 mL of air. Unfortunately (for ET drug therapy), most of the medications now prescribed for emergency situations come in prefilled syringes with built-in needles (Fig. 27-1) . This type of apparatus usually does not allow one to draw up an additional volume of air to empty the catheter of solution. Also, the needle on the prefilled syringe requires an IV adapter lock in order to utilize most catheters for injection.
3. Desired diluent solution. As previously described, the drug should be delivered in a final volume of 10 mL for adults and 1 to 2 mL for neonates and children. An adequate volume of diluent, usually normal saline, must be available. Distilled water is an acceptable alternative.
4. Desired medication to be instilled (see Tables 27-2 and 27-3) .
5. An 18- or 19-ga needle for use in drawing up the drug solution and/or for injecting the solution. Use of an 18-ga, 8.9 cm (3.5 in.) spinal needle is recommended for direct instillation of medications into the proximal end of the ET tube.
6. Alcohol wipes for cleaning vials and/or injection ports.
7. Gloves, mask, and eye protection. After instillation, the solution often refluxes out of the ET tube, making blood and body fluid precautions of paramount importance.

## PROCEDURE

Four procedures are described below. They are listed in order of generally accepted use, but definitive studies have not

**Figure 27-1** Example of a prefilled syringe, which is frequently used in endotracheal therapy.

clearly identified the best technique. Most important, the procedure of choice is the method that will deliver the medication to the patient in the most timely fashion. As stated previously, one should not delay drug administration to find the perfect piece of equipment or diluent (normal saline or distilled water are both acceptable in most cases).

It is assumed for all procedures that vials and IV adapter locks will be cleaned with alcohol wipes prior to use and that universal precautions will be practiced at all times. In addition, all patients require prior intubation (see Chapter 2) , and the ET tube should be secured to prevent the tube from being expelled if the patient coughs. If present, the cuff of the tube should be inflated.

**Use of a Catheter**

Begin ventilations with the bag-valve ventilation device with supplemental oxygen while the required drug dose is drawn up in either a 10- or a 20-mL syringe. Dilute the drug with normal saline as needed to attain a total volume of 5 to 10 mL (for adults) or 1 to 2 mL (pediatric and neonates). Draw back the plunger to add 5 mL of air to the liquid in the syringe. If the drug to be delivered is in a prefilled syringe, place an IV adapter lock on the catheter. The syringe can be attached to the catheter at this time or once the

catheter has been placed within the ET tube (Fig. 27-2) .

Interrupt the connection between the proximal end of the ET tube and the bag-valve ventilation device. Place the catheter within the lumen of the ET tube, ideally in such a manner that the distal end of the catheter extends 1 cm beyond the distal end of the ET tube. For the catheter to reach deep enough, the proximal end of the ET tube may need to be cut to a shorter length. Hold the proximal ends of the catheter and the ET tube at all times during the procedure. If it has not already been done, attach the syringe to the catheter. If external cardiac compressions are being performed, *they should be interrupted during drug delivery.* Inject the drug solution rapidly and forcefully through the catheter into the trachea followed by the 5 mL of air needed to flush the catheter of any remaining drug solution. Promptly remove the syringe and catheter from the ET tube. If the patient makes an effort to cough, place a thumb over the opening of the ET tube to prevent expulsion of the solution. As soon as possible after drug delivery, reconnect the bag-valve ventilation device with supplemental oxygen to the ET tube. Deliver five rapid ventilations to promote distal dispersion of the drug. Resume chest compressions if necessary.

**Direct Instillation into the Endotracheal Tube**

When special ET tubes or catheters are not available, the drug may be instilled directly into the proximal end of the ET tube. Studies using this technique have diluted the medication with normal saline and also flushed the tube with normal saline after the drug is instilled. [31]

While the patient is being ventilated, draw up the desired drug into a syringe (or use a prefilled syringe). Because no catheter is used, there is no need to draw up an additional volume of air into the syringe. Dilute the drug to a final volume of 5 mL (adults) or 1 mL (neonates and children) with normal saline. Attach an 18- or 19-ga needle (some authors recommend using an 8.9 cm [3.5 in.] spinal needle).

**Figure 27-2** Use of a central venous catheter for endotracheal drug delivery.

In a second syringe, draw up an equal volume (i.e., 5 mL adults or 1 mL neonates or children) of normal saline alone and attach an 18- or 19-ga needle. This will be used to flush the ET tube after drug instillation.

Interrupt the connection between the proximal end of the ET tube and the bag-valve ventilation device. Insert the needle of the first syringe (drug) into the proximal opening of the ET tube. If not using a Luer-Lok-type syringe, hold the proximal end of the needle with one hand to prevent loss of the needle into the tube. Discontinue cardiac compressions, and inject the drug solution rapidly and forcefully. Flush the tube immediately with the diluent in the second syringe. If the patient makes an effort to cough, place a thumb over the opening of the ET tube to prevent expulsion of the solution. Reattach the bag-valve ventilation device and deliver five rapid insufflations.

Resume chest compressions if needed.

**Use of Endotracheal Tubes with Irrigation/Drug-Delivery Lumens**

Unless these ET tubes are used for every intubation, their usefulness in emergent ET drug delivery is dependent on the provider's recognition prior to intubation that IV access will be problematic. If this is recognized, intubate the patient using an ET tube with monitoring lumen (e.g., Hi-Lo Jet ET tube) or with an EMT tracheal tube. While ventilating the patient with supplemental oxygen, draw up the required drug dose in either a 10- or a 20-mL syringe with an 18- or 19-ga needle attached (or use a prefilled syringe). If necessary, dilute the drug with normal saline or distilled water to attain a total volume of 5 to 10 mL (for adults) or 1 to 2 mL (pediatric and neonates). Draw back the plunger to add 5 mL of air to the liquid in the barrel of the syringe. Attach the syringe or insert the needle into the IV adapter lock on the ET tube monitoring/irrigation lumen (Hi-Lo Jet tube) or on the drug-delivery lumen (EMT tube). Discontinue chest compressions and rapidly and forcefully inject the drug solution during the inspiratory phase of ventilation (i.e., when the bag is squeezed). Deliver five rapid hyperventilations with the bag-valve ventilation device and resume chest compressions if necessary.

The advantage of this method of drug delivery is that it does not require interruption of the connection between the bag-valve ventilation device and the ET tube. In addition, it offers the theoretical advantage of allowing drug delivery during the inspiratory phase of ventilation, although at least one study has shown that this is not an important factor. [32]

**Injection Through the Endotracheal**

Tube Wall

This method of drug delivery has not yet been evaluated scientifically but has been used clinically. [55] [56] While the patient is being ventilated, draw up the desired drug into a syringe with an attached 18- or 19-ga needle (or use a prefilled syringe). No additional air needs to be added to the syringe. Insert the needle into the side of the ET tube proximally (Fig. 27-3) . Discontinue chest compressions and rapidly and forcefully inject the drug solution into the ET

**Figure 27-3** Method of drug injection through the endotracheal tube wall.

tube during the inspiratory phase of ventilation (i.e., when the bag is squeezed). Deliver five rapid hyperventilations with the bag-valve ventilation device and resume chest compressions, if necessary. As with ET tubes with drug-delivery lumens, this technique requires no interruption of the connection between the bag-valve ventilation device and the ET tube. In addition, placing an IV adapter lock on the needle allows it to be left inserted in the ET tube for use with additional medications.

# COMPLICATIONS

Reported complications of ET drug therapy are rare, due in part to the infrequent use of this technique. In addition, because most or all of the patients who receive ET drug therapy are in cardiopulmonary arrest or are otherwise critically ill, it is difficult to ascertain if an adverse outcome is the result of the therapy or the patient's underlying condition.

With regard to the techniques of ET drug administration, no serious complications have been reported. A theoretical complication is the loss of a needle or catheter down the ET tube, but this can be prevented by specifically holding the catheter or needle while instilling the drug. Thus the techniques of ET drug administration seem to provide a safe method of drug delivery.

Following ET drug administration, the administered emergency drugs may produce adverse effects. Epinephrine administered during CPR has been noted to produce prolonged hypertension, tachycardia, and arrhythmias after the return of a perfusing rhythm in both animal models [23] and human case reports. [13] It appears that this side effect is related to the depot effect, in which larger doses of drugs administered endotracheally are released slowly over time (similar to an IV drip). In addition to epinephrine, atropine and lidocaine also exhibit a depot effect when administered endotracheally. [53] No serious long-term sequelae have been reported, however, due to this effect.

A second area of potential concern with ET drug therapy is a transient decrease in arterial oxygen content during or after drug delivery. As discussed previously, if total volumes are maintained between 5 and 10 mL in adults, the effect on pulmonary function appears minimal. It should be remembered, however, that any decrease of $Pa_{O2}$ in a critically ill patient, regardless of how small or how transient, may have deleterious effects. The potential for this adverse effect should always be considered when administering drugs by the ET route, and supplemental oxygen should always be administered in an effort to improve oxygenation and offset any transient drop in arterial oxygen content that might develop.

## CONCLUSION

It is important that physicians be familiar with ET drug therapy because it may be a life-saving procedure in some emergent situations. The great variability in the effectiveness of this procedure, however, mandates that it be used only when IV or IO access is not available. Little information is available on the pharmacokinetics, pharmacodynamics, and effectiveness of medications administered via the ET route during cardiopulmonary arrest. Consequently, the ideal dose, diluent, volume, and technique have yet to be determined. Despite these limitations, ET drug therapy has been shown to be beneficial for some patients. If other access is not available, appropriate medications should be delivered via the ET route using the procedure that will ensure delivery to the patient in the shortest period of time.

# Chapter 28 - Autotransfusion (Autologous Blood Transfusion)

**Thomas B. Purcell**

Among the various afflictions that may jeopardize human life and well-being, traumatic injury affects men and women during their most productive years. [1] This fact, coupled with increasingly efficient and rapid emergency transportation systems, has resulted in growing numbers of these victims arriving at emergency facilities in potentially salvageable condition. The ensuing urgent demand for blood has often exceeded the immediately available supplies of homologous banked blood. Successful approaches to this problem have included earlier hemostasis (i.e., definitive surgery), use of volume expanders (crystalloid, colloid), and autotransfusion. Approaches currently under investigation include the use of hypertonic saline and manufactured blood substitutes.

Autotransfusion may be defined as "collection and reinfusion of the patient's own blood for volume replacement." [2] Emergency autotransfusion most often involves collection of shed blood from a major body cavity, usually the pleural space (hemothorax) and occasionally the peritoneal space. Autotransfusion in the emergency department is generally limited to acute hemothorax with clinically significant hypovolemia. The following discussion examines the advantages and potential complications of emergency autotransfusion, patient selection, available equipment, and procedural technique for several widely used devices.

## BACKGROUND

Autotransfusion has a relatively extended tradition in the Western medical literature. An early report was published in 1818 by Blundell, [3] an English practitioner who reflected on the possibility of reinfusion of shed blood after witnessing a woman exsanguinate from uterine hemorrhage. His subsequent work with autotransfusion of shed blood in dogs suggested the clinical feasibility of the procedure. In 1886 Duncan [4] used the technique without notable ill effects while reinfusing blood shed during an amputation. In 1914, the use of the technique in ectopic pregnancies was popularized by Thies, [5] and 3 years later Elmendorf [6] published a description of the first case of autotransfusion from traumatic hemothorax. Also in 1917, Lockwood [7] used the procedure for the first time in the United States during a splenectomy. In 1922 Burch [8] reviewed 164 cases of autotransfusion published over the preceding 8 years in the European medical literature, primarily out of Germany.

The discovery of ABO blood typing at the turn of the century and the institution of blood banks in the 1930s led to the almost exclusive use of homologous blood up to and following World War II. Interest in autotransfusion concomitantly declined, and only sporadic reports appeared in the literature during this period. During the 1960s and 1970s, cardiopulmonary bypass surgery generated extensive data regarding intraoperative retrieval of large quantities of blood for reinfusion. Concurrently, the Vietnam War created tremendous new demands for readily available blood in areas

remote from conventional reserves of homologous bank blood. Thus, revitalized interest, coupled with growing experience, generated the early publications of such investigators as Dyer and associates, [9] Klebanoff and colleagues, [10] [11] and Symbas and coworkers, [12] which initiated the "new era" of autotransfusion.

## ADVANTAGES

The advantages of autotransfusion over banked blood transfusion in patients who are hypovolemic from traumatic blood loss include the following:

1. There is rapid availability to the patient (collection and initiation of reinfusion can be accomplished within minutes).
2. Blood compatibility is not a problem, which avoids both untoward transfusion reactions and the problem of crossmatching uncommon blood types.
3. There is immediate reinfusion of normothermic autologous blood and consequent reduction in the life-threatening complications of hypothermia created by the administration of room-temperature fluids. [13]
4. The risk of indirect patient-to-patient transmission of infectious diseases (e.g., hepatitis, malaria, cytomegalovirus, or human immunodeficiency virus) is eliminated. [14]
5. Levels of 2,3-diphosphoglycerate (2,3-DPG) have been found to be significantly higher in autotransfused red blood cells (RBCs) than in stored homologous cells. [15] [16]
6. There are no direct complications of hypocalcemia or hyperkalemia. [17] [18]
7. There is less risk of inadvertent circulatory overload and adult respiratory distress syndrome (ARDS). [19]
8. Autotransfusion allows preservation of limited stores of banked blood, thereby ensuring their availability for other uses. [14]
9. Autotransfusion lowers the cost of medical care. [14] No blood drawing, typing, or crossmatching is required; thus, time, money, and personnel expenditures may be conserved. Davidson [20] reported the cost of autologous blood to be three- to eight-fold cheaper per unit compared with banked blood.
10. It may be acceptable to those patients whose religious convictions prohibit transfusions with homologous blood. Techniques for intraoperative or extraoperative collection of autologous blood that involve *blood storage* or *reinfusion of shed blood* are objectionable to Jehovah's Witnesses. Nonetheless, salvage when extracorporeal circulation is uninterrupted may be acceptable to many members of that religion.

## PATIENT SELECTION

### Indications

In general, all victims of severe trauma, whether blunt or penetrating, should be considered potential candidates for

autotransfusion. More specifically, Reul and colleagues [22] have described three

categories of patients for whom emergency autotransfusion is suitable. First, the ideal candidate is the patient who has sustained blunt or penetrating chest trauma, with an acute chest tube collection of 1500 mL or more of blood. A second category is the patient with immediate need but with <1 whole-body blood volume loss for whom no homologous blood, or only limited quantities, are available because of the urgency of the situation, a blood bank shortage, or a difficult crossmatch. Under these circumstances, Reul and coworkers used autotransfusion regardless of the type of injury or degree of contamination. A third category is the patient with massive blood loss (less than one whole-body blood volume) for whom autotransfusion can serve as a supplement to homologous replacement. O'Riordan [18] adds a fourth category: the trauma patient who urgently requires blood transfusion and whose religious convictions prohibit homologous transfusion. Barriot and colleagues reported their experience with hemothorax autotransfusion by the emergency medical services of the Paris Fire Brigade and demonstrated that this technique may be effectively used in the out-of-hospital setting.

It seems clinically reasonable to consider use of autotransfusion in all suitable patients who have a hemothorax and require even minimal blood replacement. In situations in which the need for homologous blood transfusion is borderline, autologous blood can be readily reinfused without the risk of complications associated with the use of banked blood. In our own emergency department, we have simplified the *indications* for initiating collection for possible autotransfusion to the following:

1. Blunt or penetrating chest trauma with significant hemothorax (500 mL or more) as suggested on a chest film
2. Multiple trauma with shock of uncertain etiology in a patient for whom immediate (prior to chest film) tube thoracotomy is contemplated
3. Emergency thoracotomy
4. Any hemothorax when there is an urgent need for blood and the patient's religious beliefs prohibit homologous transfusions

**Contraindications**

Reul and coworkers [22] also suggested the following 4 general contraindications to the use of emergency autotransfusion:

1. The presence of malignant lesions in the area of traumatic blood accumulation.
2. Known renal or hepatic insufficiency.
3. Wounds older than 4 to 6 hours (because of the theoretic problem of bacterial overgrowth).
4. Gross contamination of pooled blood, usually as a result of trauma of the gastrointestinal tract. They added, however, that "the presence of any of these contraindications was occasionally overruled by the lack of available (banked) blood."

Huth and colleagues [25] found that major combined pancreatic-proximal intestinal injury also may constitute a contraindication owing to the potential for systemic reinfusion of

large amounts of pancreatic enzymes.

On the other hand, the National Blood Resource Education Program Expert Panel [26] has limited contraindications to active infection or gross contamination and the possibility of malignant cells in the salvaged blood. Investigation has confirmed that even when using systems that separate and wash cells, tumor cells will be resuspended and reinfused to the patient. [27]

Several investigators believe that the reinfusion of limited amounts of possibly contaminated blood from the peritoneal cavity may be accomplished with an acceptable risk, [28] [29] [30] but the current consensus is that exsanguinating hemorrhage is the only acceptable indication for autotransfusion when there is recognized intestinal contamination. Klebanoff, [31] on the other hand, believes that autotransfusion has "no place" when there is extensive fecal or urinary contamination of the pooled blood. Thus, the advisability of autotransfusing possibly contaminated blood from the peritoneal cavity remains controversial (see Complications).

## EQUIPMENT AND MATERIALS

### Autotransfusion Units

Symbas and associates [32] described a simplified collection system using standard materials available in any emergency department. After insertion of a chest tube, drainage is established into a standard chest tube bottle containing 400 mL of normal saline, maintaining a suction of 12 to 16 mm Hg. (Many of the disposable plastic thoracostomy collection devices now have the ability to act as reservoirs for autotransfusion in case the need arises.) If autotransfusion is required, the collected blood in the chest bottle is reinfused in one of two ways:

1. The chest bottle may be disconnected from the pleural drainage tube and simply inverted on an IV stand for reinfusion through a filter into the patient. During infusion, a second sterile chest bottle with saline is connected to the chest tube for continuing collection.
2. After disconnection from the pleural drainage tube, the chest bottle may be connected to a standard blood collection bag and the salvaged blood transferred to this bag for subsequent reinfusion in the conventional manner. Symbas [32] reported on more than 400 patients autotransfused by this method since 1966, with no adverse effects attributable to the procedure.

Von Koch and associates [33] reported their experience with the Sorenson unit (now the Abbott Receptal system) in autotransfusing an average of 1000 mL of salvaged blood in each of 30 trauma patients. They found this unit could be assembled quickly and was easily operated, and its use resulted in minimal air-blood interfacing (a source of hemolysis). They also described the unit as "efficacious, inexpensive, cost effective and safe." Davidson [20] described in detail the step-by-step use of this system in the emergency department and characterized it as "simple to use, efficacious, cost effective and safe" for the emergency setting. Autotransfusion using this device is described in

the following section.

A unit introduced more recently, the Pleur-Evac autotransfusion system (Deknatel, Inc., Fall River, Massachusetts), is similar in concept to the Abbott Receptal system but is designed to be installed directly in series with a standard Pleur-Evac underwater seal drainage system. A disadvantage of this unit is the smaller collecting capacity (1200 mL vs 1900 mL in the Abbott Receptal system). Advantages include an overflow accommodation, which sends blood in

excess of the 1200-mL collection bag capacity automatically into a spillover collection chamber of the main Pleur-Evac unit, and an ability to monitor the patient for air leaks during collection without changing systems.

Other units suitable for use in the emergency department have recently entered the market and are described below in the Procedure section.

The Haemonetics Cell Saver (Haemonetics Corp., Natick, Mass) aspirates the patient's blood into a reservoir and brings the blood, after it has been anticoagulated, through a special suction line to a centrifuge. The centrifuge spins off the supernatant fluid, which consists of plasma that contains hemolyzed cells, free hemoglobin, fat cells, electrolytes, anticoagulant, and contaminants. When the hematocrit of the remaining blood approaches 55 to 65%, normal saline washes it clear of hemolyzed cells, and the packed and washed cells are then reinfused. Major disadvantages of the device, in the opinion of Mattox, [34] are its complexity, requiring a specially trained technician for its operation, and its cost. Use of the Cell Saver system offers the theoretical advantage of avoiding reinfusion of activated clotting factors. Brewster and colleagues believe that "this advantage is achieved at the expense of an earlier dilutional decrease of coagulation factors, which are totally lost with discarded plasma and wash fluid." [35] Therefore, the system may require the use of fresh frozen plasma and additional colloid, such as albumin, to replace the discarded plasma volume, although this is generally not required with lower infusion volumes. [36] This device is generally not suited for use in the emergency department.

Two highly simplified techniques have been described. Schweitzer and coworkers [37] reported successful autotransfusion in dogs by means of a chest tube connected to a Heimlich flutter valve (Bard-Parker, Rutherford, NJ). The valve is connected in turn to a 1900-mL Abbott Receptal blood collection bag. Drainage is entirely by gravity; no suction is applied. Similarly, Barriot and colleagues [23] [24] described the European experience with a device called a *Hemotraum* adapted for prehospital autotransfusion. Blood from the chest tube fills a 750-mL sterile bag by gravity via a 120-mum micropore filter. When full, the bag is clamped and disconnected, and the collected blood is reinfused through a 50-mum micropore filter. While this blood is being transfused, a second sterile bag is connected to the chest tube. No anticoagulant is used. Although neither of these techniques has undergone clinical trials in the United States, they do serve as indications of possible future trends in emergency autotransfusion in the battlefield, the small rural hospital, or the prehospital care setting.

**Blood Filters**

*Some form of in-line filtration is advisable during reinfusion of blood products* to reduce the danger of microembolization and resulting pulmonary insufficiency. Controversy continues regarding the relationship between the presence of microaggregates and the development of ARDS [38] ; however, most investigators advise some form of micropore filtration during emergency autotransfusion. Pore size seems to be the only issue, and recommendations range from 20 to 170 mum. [40] [41] The majority of investigators believe that a pore size of 40 mum (microns) minimizes the risk of microembolization without undue elevations in filtration pressures.

**Vacuum Suction**

*The level of vacuum suction used should be limited to minimize RBC hemolysis*. [35] Reul and colleagues [22] found that 5 to 10 mm Hg avoided hemolysis, but higher levels of suction could be used. Von Koch and associates [33] used 10 mm Hg, Davidson [20] used 20 to 40 mm Hg, Noon [40] used 30 to 60 mm Hg, and Brewster and colleagues [35] and Dyer and coworkers [9] found that levels below 100 mm Hg kept hemolysis to a minimum.

Suction pressure of 60 mm Hg or less has been preferred by most researchers for aspiration of hemothorax or hemoperitoneum, but in the operating room, adequate suction to maintain a bloodless surgical field may require a pressure well over 100 mm Hg. With most commercial systems, the manufacturer's recommendations specify a suction limitation of 150 mm Hg. [43] A second vacuum source of 300 mm Hg should be available for occasions when high-flow suction is required. [44] To minimize hemolysis, reducing the air-blood interface is as important as limiting the vacuum level. Therefore, suctioning should be from pooled blood whenever possible, with the suction tip kept well below the surface of the blood.

**Anticoagulation**

Anticoagulation of the aspirate during autotransfusion has been accomplished using several different methods. These include both local and systemic heparin, acid-citratedextrose (ACD), citrate-phosphate-dextrose (CPD), and normal saline (i.e., no anticoagulant). Local heparinization of the tubing and reservoir may lead to the formation of platelet microaggregates on the filter and in the line and systemic heparinization could lead to further life-threatening hemorrhage in an already bleeding patient.Therefore, *the use of heparin as an anticoagulant during emergency autotransfusion of the trauma patient is discouraged by most investigators*.

In several early studies, ACD was used as an alternative to heparin. [17] Raines and coworkers [41] found no clinical or laboratory evidence of intravascular coagulopathy after autotransfusion using ACD, even in patients who received more than 8000 mL of autologous blood. More recent studies report the use of CPD for extracorporeal anticoagulation. Some advantages of CPD are that it avoids the complications of

heparinization, [22] necessitates less volume as an anticoagulant, and results in less acidosis than does ACD. Reul and colleagues [22] found CPD to be well tolerated, even in large amounts.

Investigators have recommended a range of 25 to 70 mL of CPD per 500 mL of collected blood. A 1:7 ratio of CPD to blood has also been suggested. [45] [51] This compares favorably with the standard 67 mL of CPD per unit of banked donor blood. [22] Klebanoff [31] stated that CPD is the safest method of anticoagulation for autotransfusion and that the use of CPD avoids the problem of clot formation on the blood filter, thus maintaining higher platelet counts in reinfused blood.

Davidson has noted that for the average chest wound, added anticoagulant may not be required. [20] Blood retrieved from pleural and abdominal cavities frequently will not clot because it is devoid of fibrinogen, [53] likely because moderate rates of bleeding allow time for defibrination by contact with

serosal (pleural and peritoneal) surfaces and by mechanical agitation from respiratory and cardiac movements. Dog studies have documented pleural deposition of fibrin following experimental hemothorax, further substantiating this mechanism as the cause of hypofibrinogenemia in collected blood. [54] Others [12] [24] [55] report corroborating clinical findings and recommend simple reinfusion through a filter without any anticoagulant.

However, wounds of the great vessels may bleed at a rate that allows coagulable blood to enter the collection reservoir, clotting off the entire system. [20] [33] [51] In such an instance, an anticoagulant, specifically CPD, is appropriate. Thus, accepted guidelines generally include the use of CPD, which itself undergoes such rapid metabolism that anticoagulation is confined, to a large degree, to blood in the autotransfusion apparatus. Rarely, excessive use of CPD can cause citrate intoxication because of chelation of calcium and subsequent cardiac dysrhythmias. Use of insufficient or outdated CPD may result in clotting of collected blood.

# PROCEDURE

Mattox [34] set forth the properties of the ideal autotransfusion device: (1) easy and quick assemblage, (2) cost-effectiveness, (3) easy operation, (4) in-line microfiltration, (5) minimization of air-fluid interfaces, and (6) simple anticoagulation technique. Several devices currently being marketed conform to these specifications, and these are discussed in detail.

### Abbott Receptal Disposable Suction Liner System

The Abbott Receptal autotransfusion system (Abbott Laboratories, Abbott Park, IL 60064) consists of a closed, rigid, nonsterile plastic canister into which a gas-autoclaved plastic bag is placed for blood collection. The canister can be mounted on an IV pole and connected to a vacuum regulator valve for control of negative suction pressure. The collection bag is placed in-line with disposable collection tubing that has a separate inlet

valve for admixture of anticoagulant and aspirated blood. This inlet is connected via sterile tubing to a bottle of CPD (Figs. 28-1 (Figure Not Available) and 28-2) (Figure Not Available) .

**Collection**

1. To collect autologous blood from a hemothorax, first open the included "Trauma Drainage Tubing Set" containing one 36 Fr chest tube, latex drainage tubing ( *B* and *C*, Fig. 28-1) (Figure Not Available) , and a male-to-male connector *(D)*.

    While tube thoracostomy is being performed in the usual manner, the burette set *(A)* is connected to the CPD bottle, and the burette is filled with 150 mL of CPD.

2. Connect the yellow-tipped *(E)* end of the latex drainage tubing (the end with the side port) to the inlet port *(F)* of the red liner cap attached to the collection canister (see Figs. 28-1 (Figure Not Available) and 28-3) (Figure Not Available) . Then remove the protective cap from the side port and connect the anticoagulant (CPD) administration line (see Fig. 28-2) (Figure Not Available) . Prime the liner with 50 mL of CPD from the burette.
3. Connect the downstream suction hose ( *H*, Fig. 28-1) (Figure Not Available) to wall suction and turn wall suction to maximum. Be sure that the regulator on the autotransfusion stand does not exceed the preset 60 mm Hg during collection (100 mm Hg in special situations such as post-thoracotomy); otherwise, excessive hemolysis of RBCs may result.
4. When the chest tube is in place, connect the latex drainage tubing and begin collection. During collection, stay ahead of the accumulating blood volume with the CPD in 50-mL increments. Always keep the ratio no less than 1 part CPD to 10 parts blood (1:7 ratio of CPD to blood is recommended by the manufacturer); otherwise, the collected blood may clot, especially with massive ongoing hemorrhage. Do not overfill the liner bag; it will overflow, spilling blood into the regulator valve.

**Reinfusion**

1. Prepare a standard Y-type blood infusion line with a high-capacity 40-mum in-line filter, prime the line and filter with normal saline, and connect it to a large-bore IV access (14-ga or larger) (Figs. 28-4 (Figure Not Available) and 28-5) (Figure Not Available) .
2. When the liner bag is full, temporarily clamp the chest tube, discontinue suction, and remove the yellow end of the latex drainage tubing *(E)* from the red liner lid. The liner lid tubing connector *(J)* is now removed from the canister tee *(K)* (Fig. 28-6) (Figure Not Available) and connected to the inlet port *(F)* of the liner cap, thus sealing the top of the collection lid (Fig. 28-7) (Figure Not Available) .
3. Remove the liner assembly from the canister by pushing upward on the thumb tab (Fig. 28-7) (Figure Not Available) , lift out the liner bag, invert the bag, and unscrew the protective cap *(N)* over the bottom stem of the liner. Now insert the free recipient arm ( *L*, Fig. 28-4) (Figure Not Available) of the Y-tube infusion line into the stem of the collection bag (see Fig. 28-4) (Figure Not Available) , and

hang the liner bag on the IV stand by the attached tab (M) (see Fig. 28-5) (Figure Not Available) . Before infusion, briefly disconnect the liner lid tubing connector ( *J*, Fig. 28-5) (Figure Not Available) , *vent all air from the bag* (to eliminate the possibility of air embolism), and then reconnect it to the inlet port.

4. Gravity flow, manual squeezing of the liner bag, or an in-line roller pump may be used to hasten reinfusion. Although some reports [20] [33] mention the use of encircling pneumatic blood pumps during reinfusion, Abbott cautions that such devices may damage the pump or rupture the liner bag.

5. During reinfusion, autologous blood collection may be continued with a second liner bag. Be sure that the new liner bag is fully extended before placing it into the canister (Fig. 28-8) (Figure Not Available) . If the bag is crumpled at the top of the canister, blood may be sucked directly into the regulator valve. Insert the new liner into the canister, and snap the lid in place with the thumb tab directly over the canister tee (Fig. 28-9) (Figure Not Available) . The unit is now ready for collection assembly as previously outlined.

## Boehringer Autovac System

A unique advantage of the Boehringer Autovac (Boehringer Laboratories, Inc., Norristown, PA 19401) is the optional integral vacuum regulator built into the cap. This feature allows direct attachment to a wall vacuum without an external regulator. It automatically limits applied suction to a

**Figure 28-6** (Figure Not Available) Preparation for reinfusion. Removal of liner lid tubing connector (J) from canister tee (K). Inlet port (F) is shown. *(Courtesy of Abbott Laboratories, Abbott Park, IL 60064. Reproduced by permission.)*

maximum of 100 mm Hg, thereby minimizing RBC hemolysis. The collection line has been enlarged to ¼-inch in diameter, which decreases the surface area to which RBCs are exposed and decreases blood velocity as it travels through the line (thereby further limiting hemolysis). The number of connections on the collection line has been reduced to 1, and the male connector has a skirt shield, reducing the chances of inadvertent contamination through contact with nonsterile surfaces. The collection bag is prepackaged within a disposable rigid plastic canister and will hold up to 1000mL of collected blood. Inside the collection chamber is a shutoff system consisting of a hydrophobic filter which, upon contact with blood or any liquid, quickly occludes preventing overflow into any downstream component (e.g., wall suction regulators).

### Collection

1. First, the vacuum line is attached to the connector on the canister (Fig. 28-10) (Figure Not Available) . Models not equipped with the optional integral regulator must be attached to a wall regulator that has been set at no greater than 100 mm Hg vacuum.

2. The canister is anticoagulated by injecting anticoagulant through a port on top of the canister. The Boehringer Company recommends (and offers for sale) anticoagulant citrate dextrose solution A (ACD-A), a solution containing 0.73 g of citric acid, 2.2 g of sodium citrate and 2.45 g of dextrose per 100 mL. Initially 40

mL is injected into the bag, and as collection proceeds, ACD-A is added to maintain a proportion of 1:5 to 1:10 ACD-A to blood.
3. During collection, the canister is periodically agitated to facilitate mixing of blood and anticoagulant.
4. When full, blood will come into contact with the hydrophobic filter at the top of the canister, automatically shutting off the system.

**Reinfusion**

1. Engage both slide clamps at the top of the canister.

   Both collection and vacuum lines are now occluded, creating a closed system.

2. Disconnect the canister from suction and collection lines. If further collection is desired, another canister can now be attached to these lines.
3. The flexible blood bag is now removed from the rigid canister by first removing the white safety tape and then popping the lid from the lower portion of the canister.
4. While keeping the bag upright, the slide clamp over the vacuum connector is now temporarily loosened and the bag gently squeezed to expel any residual air out through the filter shutoff mechanism. Then the slide clamp is re-engaged.
5. The bag may now be attached to a blood administration set in the usual fashion (Fig. 28-11) (Figure Not Available) . The manufacturer recommends the use of an in-line microaggregate filter (20 to 40 mum).
6. An external pneumatic cuff around the bag may be used to increase flow rates, but cuff inflation pressures should not exceed 300 mm Hg.

## Pleur-Evac Autotransfusion System

The Pleur-Evac autotransfusion device (Deknatel, Inc., 600 Airport Road, Fall River, MA 02720) consists of a sterile, single-use, disposable, rectangular-shaped, flexible polyvinyl

**Figure 28-11** (Figure Not Available) Boehringer reinfusion apparatus. *(Courtesy of Boehringer Laboratories, Inc., Norristown, Pa. Reproduced by permission.)*

chloride blood collection bag supported by a rigid metal frame. The bag and frame are designed to attach in series directly to a standard Pleur-Evac underwater seal drainage unit. On a newer version of the drainage unit, the water suction control chamber is replaced by a dry suction control with a dial that may be set to regulate suction between 0 and 40 cm $H_2$ O, regardless of the amount of source suction applied. Inside the collection bag in line with the incoming drainage tube is a 200-mum nylon mesh filter. Attached to the collection bag are two latex tubes, one (red tipped) for collecting shed blood from the drainage site and one (blue tipped) for connection to the Pleur-Evac drainage unit. An injection port is provided on top of the autotransfusion bag for the

addition of anticoagulant to collected blood.

**Collection**

1. The Pleur-Evac underwater seal drainage unit (Fig. 28-12) (Figure Not Available) is first prepared in standard fashion and connected to a source of suction. Slide the metal hanger over the patient drainage tubing port on the right-hand side of the unit (Fig. 28-13) (Figure Not Available) , and pull it down flush with the top and side of the drainage unit.
2. Unwrap a replacement autotransfusion system (ATS) bag and fit it into the wire frame provided (Fig. 28-14) (Figure Not Available) . Close both white clamps on the bag tubing, and place the frame and bag on the wire hanger.
3. Clamp the drainage tubing coming from the patient.
4. Remove the red protective cap from the collection tubing ( *B*, Fig. 28-12) (Figure Not Available) on the ATS replacement bag and connect it to the patient chest drainage tubing *(C)* using the red connector.
5. Remove the blue protective cap from the suction tubing *(D)* on the ATS replacement bag and connect to the underwater seal drainage unit using the blue connector.
6. Using a syringe and an 18-ga (or smaller) needle, inject anticoagulant through the rubber diaphragm *(E)* on the ATS bag cap. The manufacturer of the Pleur-Evac unit does not offer recommendations regarding specifics of anticoagulation of blood collected in the unit; however, the method outlined for the Abbott Receptal system may be applied to this unit as well (see step 4 under Abbott Receptal System--Collection).
7. Open all clamps; make sure all connections are airtight. The system is now operational.

**Reinfusion**

1. Prepare a standard Y-type blood infusion line with a high-capacity 40-mum in-line micropore filter, prime the line and filter with normal saline, and connect it to a large-bore IV access (14-ga or larger) (see Fig. 28-5) (Figure Not Available) .
2. When the ATS bag is full, use the negative-pressure relief valve (located on top of the drainage unit) (see Fig. 28-12 (Figure Not Available) *F*) to reduce excessive suction in the unit, and close the white clamps on the chest drainage tubing and ATS bag.
3. Disconnect all connections to the autotransfusion bag.
4. Attach the male (blue) and female (red) connectors on top of the autotransfusion bag to each other, and remove the bag from the drainage unit by spreading and disconnecting each metal support arm.
5. Slide the autotransfusion bag out of the wire frame and invert the bag so that the spike port ( *G*, Fig. 28-12) (Figure Not Available) points upward. Remove the protective cap. Insert the free recipient arm of the Y tube infusion line into the spike port using a constant twisting motion.
6. Invert the autotransfusion bag and suspend it from an IV pole (Fig. 28-15) (Figure Not Available) .
7. Reinfusion using the Pleur-Evac autotransfusion bag may be assisted using a

pneumatic pressure blood pump, not to exceed 150 mm Hg infusion pressure. However, if a pneumatic pump is used, all air in the bag must be removed before infusion to minimize the risk of air embolism. To accomplish this, the red and blue connectors may by disconnected temporarily, one clamp opened, and the bag slowly squeezed until all air is out of the unit. Then the clamp is closed again, and the red-to-blue connection reestablished.

8. During reinfusion, autologous blood collection may be continued with a second ATS bag, repeating steps 2 through 7 under Collection.

**Continuous Reinfusion**

The Pleur-Evac system may be set up for continuous collection and simultaneous reinfusion of collected blood as follows:

1. Set up a blood administration set, microaggregate filter, and IV pump.
2. Prime the filter, drip chamber, and administration set with normal saline and then remove the bag of saline.
3. Spike the autotransfusion collection bag and connect it to the blood administration set.
4. Use the IV pump to prime the filter, drip chamber, and infusion line with blood. Make sure no air is in the line.
5. Attach the primed administration set to the patient's IV line.
6. To prevent air from entering the system, keep at least 75 mL of blood in the collection bag at all times. If this is not done, air embolism may result. (When an infusion pump is used in this fashion, air embolism is a significant risk--see Nonhematologic Complications below).
7. If continuous reinfusion is used, maintenance of proper proportions of anticoagulant to collected blood may become problematic.

## Thora-Seal-III Autotransfusion Chest Drainage System

The layout of the Thora-Seal-III system (Sherwood Medical, St. Louis) (Fig. 28-16) (Figure Not Available) is similar to that of the Pleur-Evac system. Suction is limited by a water seal chamber to no more than 25 cm $H_2$ O (equivalent to 18 mm Hg). However, occlusion of the suction control portal ( *C*, Fig. 28-16) (Figure Not Available) above the chest drainage unit will create a closed system, allowing direct connection to wall suction and attainment of slightly

higher suction levels when desired. It should be noted that if this is done, suction must not exceed 40 mm Hg, since the reinforced collection bag *(D)* will begin to collapse above this level. Reinfusion may be assisted with a standard infusion cuff, but the manufacturer advises that reinfusion pressures be limited to no more than 150 mm Hg.

This system also may be set up for continuous reinfusion in a fashion similar to that described above. Caveats regarding the danger of air embolism and difficulty of maintaining proper proportions of anticoagulant to collected blood similarly apply.

**Thora-Klex Chest Drainage System with Autotransfusion**

The Thora-Klex system (Davol, Inc., a subsidiary of C. R. Bard, Inc., Cranston, RI 02920) (Fig. 28-17) (Figure Not Available) has an in-line configuration with a standard chest drainage system similar to the Pleur-Evac system. The Thora-Klex does not incorporate a water seal chamber. Instead, there is a suction control dial (which reads centimeters of water rather than millimeters of mercury) built into the top of the unit (Fig. 28-18) (Figure Not Available) . A negative pressure indicator within the system indicates at all times the degree of suction inside the chamber. The suction may be set up to 40 cm $H_2$ O (29 mm Hg) and a built-in suction relief valve limits absolute suction to a maximum of 50 cm $H_2$ O (37 mm Hg).

Design of the unit allows unimpaired collection even if the unit is accidently tipped over. The autotransfusion bag has a capacity of 1000 mL, and like the Thora-Seal unit, the system may be set up for continuous collection/reinfusion (the caveats mentioned above regarding potential for air embolism and difficulties with maintaining blood/anticoagulant proportions apply similarly to this system).

The collection bottle is used for reinfusion through a blood administration system (Fig. 28-19) (Figure Not Available) . The in-line filter should be changed when the blood flow into the collection bottle slows at maximum vacuum levels (Fig. 28-20) (Figure Not Available) .

**Additional General Autotransfusion Information**

1. Use each liner bag only once.
2. After reinfusing a total of 3500 mL, or 7 units, of autologous blood, it has been suggested that 1 unit of fresh frozen plasma be given for every 2 units (1000 mL) of autotransfused blood. [41]
3. To minimize risk from bacterial overgrowth, collected blood must not be allowed to stand for prolonged periods of time before reinfusion. Some authors [45] [51] [56] advise a limit of no more than 4 hours between collection and reinfusion. The age of collected blood should be calculated from the time of injury, and reinfusion of blood older than 4 to 8 hours should be considered hazardous. Because one is performing the procedure for significant hypovolemia in the emergency department, the collected blood should generally be transfused as soon as the collection bag is full.
4. If some or all of the collected blood becomes clotted in the liner bag, the blood should be discarded.
5. The blood filter used during reinfusion is changed as needed (usually after each 1000- to 2000-mL transfusion). In practice, the need for a new filter will become apparent as perfusion pressures increase and flow rates visibly slow down.

## COMPLICATIONS

Complications from autotransfusion, which generally are clinically insignificant if the

proper technique is followed and if <3000 mL of blood is reinfused, may be categorized as hematologic and nonhematologic (Table 28-1) .

## Hematologic Complications

The most frequent hematologic consequence of autotransfusion is thrombocytopenia. Samples taken from collected autologous blood generally show very low platelet counts. However, the number of platelets found in this blood is still significantly greater than that found in banked blood. [55] Until patients receive more than 3500 mL of autologous blood, in vivo platelet counts, although depressed in all patients, do not drop below 60 × 10 [9] /L [23] [32] [35] ; above this level, trauma surgery can be satisfactorily performed. [56] Although those platelets collected from autotransfusion reservoirs function abnormally when tested in vitro by aggregation or serotonin uptake and release, postinfusion samples drawn from patients aggregate normally. [41] However, at least one study conducted with dogs indicates that significant in vivo platelet

| **TABLE 28-1** -- Potential Complications of Autotransfusion |

| Bacteremia |
| Sepsis |
| Microembolism |
| Air embolism |

dysfunction may appear when autotransfused volumes exceed an amount equivalent to 1 total blood volume. [16] Thus, platelet counts should be followed and significant thrombocytopenia treated with platelet infusion.

The most common coagulation factor abnormality after autotransfusion is hypofibrinogenemia, especially when the volume of autologous blood used exceeds 4000 mL. Because of the liver's capacity to replenish fibrinogen rapidly, the low postautotransfusion levels have not proved to be clinically significant. [22] [24] [51] Yet some investigators [22] believe that hepatic insufficiency is a relative contraindication to autotransfusion unless fibrinogen is supplemented.

Symbas and colleagues extended their work with laboratory dogs to the clinical study of victims of traumatic hemothorax. They found no clinical evidence of coagulopathy following autotransfusion as long as the volume collected and reinfused remained equal to or less than one half the patient's total blood volume. In those few patients who required a larger volume autotransfused, a proportional decrease in platelets and fibrinogen occurred, requiring subsequent correction with fresh frozen plasma and platelet packs. Other investigators [17] [20] have confirmed these findings and have shown that both platelet and fibrinogen levels return to normal by 48 to 72 hours, without replacement therapy. Similarly, elevations in prothrombin and partial thromboplastin

times, which were encountered routinely, were not clinically significant. These coagulation abnormalities also self-corrected within 48 to 72 hours. On the other hand, Schonberger and colleagues found that intraoperative autotransfusion of more than 800 mL shed blood may provoke a significant derangement of hemostasis. [58]

Hemolysis occurs with autotransfusion in part because of prolonged exposure of the cells to serosal linings of the traumatized body cavities. [59] Hemolysis also results from mechanical factors during collection and reinfusion, such as high vacuum pressures during aspiration, roller pump trauma, or excessive exposure to air-fluid interfaces. [22] An elevated plasma-free hemoglobin is a consistent finding in patients who have received autotransfusions.

Most samples of blood taken from the autotransfusion reservoir have free hemoglobin levels of <1.0 g/L, but some levels have been reported to be as high as 13.9 g/L. [50] Clinically, patient plasma-free hemoglobin values immediately after autotransfusion range from 0.1 to 1.0 g/L. When the binding capacity of haptoglobin is saturated and the threshold of tubular resorption of hemoglobin is exceeded, hemoglobinuria is seen. This threshold corresponds to a plasma-free hemoglobin concentration of 1.0 g/L. [60]

In the past it was believed that elevated levels of free hemoglobin following hemolytic transfusion reactions caused renal failure by precipitation of hemoglobin in and obstruction of renal tubules. However, more recent evidence suggests that the mechanism of renal failure in this setting is independent of free hemoglobin. Rather, it is a result of an antigen-antibody-induced intravascular coagulation that, compounded by vasoconstriction and hypotension, leads to renal ischemia. [61] Indeed, it has been shown that "massive hemoglobinuria may follow the transfusion of immunologically compatible hemolyzed RBCs with minimal symptoms and a benign outcome" and that isolated free hemoglobin levels of up to 130 g/L may be tolerated without renal compromise. [62] Even though renal failure as a direct consequence of autotransfusion has not been reported, [31] transient elevations in serum creatinine do occur, [18] and in the presence of shock and systemic acidosis, acute tubular necrosis remains a potential complication. [60] Some researchers [22] believe that renal insufficiency is only a relative contraindication to autotransfusion and may occasionally be overruled by the lack of available blood.

Finally, the hematocrit falls in direct proportion to the quantity of blood transfused, averaging an approximate drop of 10 to 20%. [22] [32] [29] However, nontraumatized RBC survival has been reported to be normal in all cases studied.

In general, although coagulation problems should be anticipated, they have not proven to be clinically important when volumes of autotransfused blood remain below 2000 mL in adult patients. [51] However, when reinfused volumes exceed 3500 mL, [41] laboratory evidence of a dilutional coagulopathy may become evident. When volumes of autotransfused blood are greater than the patient's total blood volume, animal studies suggest that there is increasing risk of a true consumptive coagulopathy. [16]

Recommendations regarding those infused volumes of autologous blood that should trigger replacement therapy of fresh frozen plasma or platelets range from 25% of total

blood volume (about 1250 mL in a 70-kg adult) [54] to 3500 mL. [41] Others advise reliance on laboratory tests and clinical findings rather than a set protocol based on volume exchanged. [51] Prudent clinical judgment dictates application of the more liberal guidelines for replacement therapy in those patients with extensive hepatic injury, intractable shock, or ongoing losses requiring immediate surgical intervention.

## Nonhematologic Complications

The theoretic risk of sepsis after the administration of potentially contaminated blood always exists within the nonsterile surroundings of the typical emergency department resuscitation area. Experience has shown this risk to be minimal after competent autotransfusion of an isolated hemothorax, [11] [17] [31] and there is *no* evidence to suggest that routine prophylaxis with systemic antibiotics is beneficial in this situation.

The issue of whether to autotransfuse shed intraperitoneal blood, however, is somewhat more complex than in the case with hemothorax. Recovery and reinfusion of hemoperitoneum per se has proved to be relatively safe, and Klebanoff and associates have concluded that "for contaminant-free conditions at least, as in ruptured ectopic pregnancies, ruptured spleen and liver, traumatic hemothorax, and vascular surgery, autotransfusion can be performed readily to reduce the need for homologous blood replacement." [11]

Reinfusion of autologous blood with possible enteric contamination is still considered by most investigators to be ill advised in all but the most desperate of circumstances, such as in the patient who will exsanguinate before homologous blood can be made available. If contaminated blood is infused, systemic antibiotics should be given. [30] [51] [63] Several small series describing collection and reinfusion of intestinally contaminated hemoperitoneum have been reported. [28] [63] [64] [65] [66] The overall mortality rate among this selected group approximates 20%, not unexpectedly high considering the severity of associated injuries. Experimental studies with dogs also show that autotransfusion of hemoperitoneum contaminated by intestinal contents, urine, or bile is tolerated. [11] [29]

Another complication, microemboli secondary to platelet microaggregation or fat emboli, has largely been eliminated by the use of micropore filters. [22] [35] [41] In most instances, during reinfusion of collected blood, there is a mild increase in screen filtration pressures, indicating the formation of microemboli trapped by the filter. [35] There has been no clinical evidence of pulmonary insufficiency or unexplained elevation of the alveolar-to-arterial oxygen gradient that might be attributed to the passage of microemboli beyond the micropore filter systems. [22]

Air embolism has been reported sporadically as a complication of autotransfusion. [17] [64] [67] [68] This uncommon but often fatal complication has been associated, in all cases reviewed, with autotransfusion systems using automated roller pump units in which the aspirate reservoir was inadvertently allowed to run dry. Air embolism with gravity or with a manually assisted technique is rare.

Available data indicate that although autotransfusion is not free of complications, the risk-to-benefit ratio weighs heavily in its favor in the resuscitation of selected trauma

victims. Klebanoff and coworkers reviewed the evidence as of 1970 and determined that "in over 1000 documented cases of autotransfusion in the Western literature, not a single death or major complication was attributed directly to the transfusion." [11] Symbas [32] reported autotransfusing more than 400 patients with traumatic hemothorax without any significant morbidity related to the procedure. Mattox and associates [17] reported autotransfusing 69 patients an average of 3.9 units each, with only 1 death (from air embolism) directly attributable to the procedure.

## CONCLUSION

Autotransfusion, a technique more than 100 years old, has become a subject of renewed interest in the emergency setting. The previously feared complications of hematologic or metabolic embarrassment and sepsis have not proved to be of clinical significance when appropriate patient selection and careful technique are followed. In addition, the use of

autologous blood has several advantages over the transfusion of stored homologous blood in the emergency patient, including ready availability of compatible blood, homeostasis of core temperature, higher levels of 2,3-DPG in RBCs, and cost-effectiveness. Autotransfusion has been endorsed by the Council on Scientific Affairs of the American Medical Association as a procedure that has been found to be "effective, safe and cost effective for many trauma and surgical patients" when used by experienced health care providers. [14] Although the technique is not totally free of complications, the benefits to be gained from autotransfusing the selected trauma patient outweigh the relatively limited risks.

# Chapter 29 - Transfusion Therapy: Blood and Blood Products

**Douglas A. Propp**

Transfusion of whole blood or its components (red cells, white cells, platelets, whole plasma, or plasma fractions) is indicated to compensate for certain deficiencies manifested by patients. The indications for the transfusion of *whole* blood have virtually vanished, as recent technical advances have made specific component replacement more feasible. Appropriate administration of blood products may be life saving in some emergency circumstances; it may also be indicated as a prophylactic measure in less urgent situations. By law, transfusions can be given only by a physician; potential life-threatening complications can result, as is true of any intravenous (IV) infusion.

## BACKGROUND

### Blood Groups

In the 17th century, radically daring physicians were experimenting with the transfusion of blood from animals into humans to treat a variety of ills. Around the beginning of this century it became obvious that only human blood was fit for humans. Landsteiner found that most human serum contained naturally occurring substances that reacted with the red blood cells of some, but not all, other humans, thereby discovering the ABO red cell antigen-antibody system.

### Red Cell Antigens and Antibodies

An integral part of the red blood cell (RBC) membrane is a series of glycoprotein moieties, or antigens, which give the cell an individual identity. Two different genetically determined antigens, type A and type B, occur on the surface of RBCs. The RBCs of any individual may have one, both, or neither of these antigens. Because the type A and type B antigens on the cell surface make the RBC susceptible to agglutination, these antigens are termed *agglutinogens*. The presence or absence of the agglutinogens makes up the ABO blood group classification. If neither the A nor the B agglutinogen is present, the blood group is O. When only type A agglutinogen is present, the blood is group A, and when only type B agglutinogen is present, the blood is group B. When both A and B agglutinogens are present, the blood is group AB. The relative frequencies of the different blood groups are listed in Table 29-1 (Table Not Available) .

Genes on adjacent chromosomes determine the presence or absence of agglutinogens and hence the individual's specific ABO blood group. These allelomorphic genes can be only one of the three different types--that is, A, B, or O--allowing for six possible combinations of genes (OO, OA, OB, AA, BB, and AB). There is no dominance among the three different allelomorphs; however, the type O is basically functionless, in that it causes such weak agglutination that it is normally insignificant. The different combinations of genes signify the individual's genotype, and each person is one of six

different genotypes. The resultant blood groups for the various genotypes are listed in Table 29-2 (Table Not Available) .

When type A agglutinogen is *absent* on a person's RBC, antibodies known as anti-A spontaneously develop in the plasma. Likewise, when type B agglutinogen is *absent*, anti-B antibodies develop in the plasma. When the blood is group O, both anti-A and anti-B antibodies develop. These antibodies are termed *agglutinins*. It follows, then, that group AB blood, which contains the agglutinogens A and B, contains no agglutinins at all in the plasma. Immediately after birth, the quantity of agglutinins in the plasma is near zero, but titers begin to develop in the first year of life and reach their maximum titer when the individual is between 8 and 10 years of age. This titer gradually declines throughout the remaining years of life.

The agglutinins are gamma-globulins of the IgM and IgG types and are probably produced by exposure to agglutinogens in food, bacteria, or exogenous substances other than blood transfusions. The antibodies (agglutinins) in the plasma of one blood type react with the antigens (agglutinogens) on the RBC of another blood type. This initiates the agglutination and hemolysis that are encountered in a transfusion reaction. Many other antigenic proteins (as many as 300 of different potency) are present in the RBCs of different persons. Some are of academic or legal importance, whereas others are important for their ability to produce transfusion reactions.

Clinically, the importance of antibodies directed against RBC antigens is determined by their frequency and whether they can cause RBC destruction in the circulation. The ABO system is the most important. With the first transfusion of ABO- *incompatible* blood, severe, potentially fatal reactions can occur. The Rh system is likewise very important, because there is a high likelihood (30 to 50%) that an Rh(D)-negative person will form antibodies after exposure to Rh-positive RBCs; these antibodies are then capable of causing severe hemolysis when RBCs containing the antigen are transfused a second time. Of the 40 antigens in the Rh system, D is the most antigenic, but others can also stimulate the production of antibodies in recipients lacking the antigen (e.g., E), thus complicating future transfusions. Other antigen systems in which antibodies could potentially cause hemolytic reactions are the Kell (K and k alleles), Duffy ($Fy_a$ and $Fy_b$ ), Kidd ($Jk_a$ and $Jk_b$ ), and MNS (M and N; closely linked S and s) systems. Other antigen systems are very rarely important in transfusion therapy.

## Crossmatching

Compatibility testing, or *crossmatching*, is the procedure by which the RBCs and serum of the donor unit of blood are mixed, respectively, with the serum and RBCs of the recipient to identify the presence of any antibodies and, hence, the potential for a transfusion reaction. These antibodies, after attaching to the appropriate RBC surface antigen, have the potential to cause agglutination and hemolysis of either donor or recipient RBCs. This hemolysis may be immediate or delayed. "Major" and "minor" crossmatch procedures are outlined in Table 29-3 . The end point of all crossmatches is the presence of RBC agglutination (either gross or microscopic) or hemolysis. Testing is performed immediately after mixing, after incubation at 37 °C for varying times, and with

and without an antiglobulin reagent to identify surface immunoglobulin or complement. Each unit of blood product, when properly crossmatched, can be administered with the expectation of safety.

## Transfusion Reactions

*Most serious transfusion reactions occur because of patient-blood product misassignment.* When incompatible blood is given, the result to the patient may range from no effect to death. If the recipient does *not* have antibodies (naturally occurring or acquired) directed against the foreign RBC antigen received, there will be no immediate reaction, but antibodies to the infused blood may develop within weeks, which will limit the safety of subsequent transfusions from the same donor or same antigenic type. If the recipient's serum *has* preformed antibodies directed against the donor RBCs (incompatibility in the *major* crossmatch), within seconds or minutes the recipient will begin to hemolyze the transfused (donor) cells.

In most cases of major crossmatch reactions, RBCs of the *donor* blood are agglutinated and hemolyzed. It is very rare that the transfused blood ever produces agglutination of the recipient's cells. Donor blood is affected because the plasma portion of the donor blood immediately becomes diluted by the plasma of the recipient, thereby diluting the titer of the infused agglutinins to a level too low to cause agglutination. Because the recipient's plasma is not diluted to any significant degree, the recipient's agglutinins can still agglutinate the donor cells. Mismatched blood groups eventually cause hemolysis of the RBCs. Occasionally, antibodies cause immediate hemolysis. More often, the cells first agglutinate, then are trapped in peripheral vessels; over a period of hours to days they become phagocytized, releasing hemoglobin into the circulatory system.

Clinical manifestations of acute hemolysis are chills, fever, tachycardia, abdominal pain, back pain, hypotension, fainting, and an anxious "feeling of impending doom." From the liberation of intracellular material associated with hemolysis, vasoactive substances may aggravate a preexisting hypotension and cause shock; other substances may precipitate disseminated intravascular coagulation, and high-output cardiac failure, or anoxic acute renal failure may result. Hemolytic transfusion reactions are estimated to occur once per every 6000 blood units transfused, with a fatality rate of 1 per every 100,000 units transfused.

An incompatibility in the *minor* crossmatch usually causes no serious reaction, although the recipient's (patient's) red cells could be hemolyzed if the titer of the antibody were sufficiently large. Even when major and minor crossmatch compatibility indicates the safety of a transfusion, a delayed hemolytic transfusion reaction can occur days to weeks later. Usually seen in multiply transfused patients (or in multigravida women), these reactions may be unavoidable without complete RBC antigen typing, a procedure occasionally indicated for recipients of numerous repeated transfusions. Fortunately, 90% of transfusions are now given as packed RBCs

| | **Major Crossmatch** | **Minor Crossmatch** |

that contain a small volume of plasma, minimizing the chance for a transfusion reaction due to donor sensitization.

Additional antibodies *not* caused by sensitization from transfused RBCs include autoantibodies (both cold- and warm-reacting) and various agglutinins. Autoantibodies can be "cold," reacting with red cells *more strongly at 4 °C* than at 37 °C. These antibodies are common and are usually harmless; however, they may be associated with disease states in higher titers (e.g., anti-I in *Mycoplasma* infections). If active at higher temperatures (up to 28 to 32 °C), pathologic cold antibodies may cause hemolysis or may even lead to enough RBC agglutination to cause obstruction of blood flow through the small vessels of the hands and feet on exposure to cold. These would also be present and identifiable at 37 °C. The primary significance of cold antibodies stems from their ability to complicate crossmatching procedures in the blood bank.

Warm antibodies, reacting *more strongly at 37 °C* than at lower temperatures, can be harmless or can be responsible for a hemolytic anemia of variable severity. Characteristics of the IgG antibody itself determine its significance to the patient. Usually harmless warm autoantibodies that can occasionally cause hemolysis are seen in patients taking alpha-methyldopa. Harmful warm autoantibodies are encountered in approximately 80% of patients with autoimmune hemolytic anemia.

Additional problems in pretransfusion testing may occur with antibodies directed against various substances that can attach themselves to the RBC surfaces and can cause

agglutination of the "innocent bystanders." Examples are the fatty acid-dependent agglutinins; penicillin and cephalosporin antibodies; bacterial polysaccharides; and nonspecific agglutination associated with a high erythrocyte sedimentation rate, caused by high levels of the acute-phase reactants fibrinogen, alpha2 -macroglobulin, and IgM. A delay in pretransfusion testing may occur when the blood bank has to undertake procedures to identify various proteins on RBC surfaces to ascertain their clinical significance.

## Miscellaneous Transfusion Problems

Pyogenic transfusion reactions, such as fever and chills, are rather common and result from the presence in the donor plasma of proteins to which the recipient is allergic. Full-blown anaphylactic reactions occasionally result.

Theoretically, citrate salts, which are the usual anticoagulants in donor blood, may combine with ionized calcium in the plasma, producing hypocalcemia. In clinical practice, the hemodynamic consequences of citrate-induced hypocalcemia are minimal, although the Q-T interval may be prolonged on the electrocardiogram (ECG) with citrate infusion. Supplemental calcium administration is usually not necessary even during massive blood replacement as long as circulating volume is maintained, because the liver is able to remove citrate from the blood within a few minutes. Alterations in this recommendation may be necessary in the presence of severe liver disease.

## Infectious Complications of Transfusions

Sepsis is of theoretical concern in blood component therapy because 0.1% of all transfusions may transmit virulent bacteria. However, sepsis is an uncommon occurrence because both citrate preservative and refrigeration kill most organisms. Concern over sepsis has governed the decision to complete transfusions within 4 hours and to return unused blood products to the blood bank refrigerator for future use only if they have been out of the refrigerator for <30 minutes. The virulent pathogens involved are most commonly gram-negative organisms.

Most blood products retain the ability to transmit hepatitis. Ninety percent of the time, the etiologic agent is hepatitis C. The customary incubation period for this agent following infusion is 2 to 12 weeks, although 80% of patients are anicteric. The likelihood of developing post-transfusion hepatitis ranges from 1 per 100 to 1 per 3000 units of blood administered. Up to 20% of patients developing chronic hepatitis ultimately develop liver failure. Since 1991, blood donors have been tested for hepatitis C, although the test is relatively inaccurate and has a positive predictive value of only 40%. In 1992, the FDA approved the use of interferon alpha2b for the treatment of selected cases of chronic hepatitis C infection.

Although syphilis may theoretically be transmitted by transfusion, *Treponema pallidum* does not survive when refrigerated or when placed in a citrated medium. Only fresh blood or platelet transfusions are of concern. The incubation period is 4 weeks to 4 months, and the initial clinical manifestation is a rash. Although controversial because of high rates of false-positive and false-negative results, many blood banks still test for

positive *T. pallidum* serology.

Both cytomegalovirus and Epstein-Barr virus can be transmitted through transfusions. A mononucleosis-like syndrome occurring 2 to 6 weeks after a transfusion is suggestive of the presence of either of these agents. Blood products with negative serologic findings for both of these agents should be used for seronegative recipients in high-risk groups, such as pregnant females, premature or low-birth-weight newborns, marrow or organ transplant recipients, and immunosuppressed patients.

The likelihood of transmission of malaria through blood products is minimal because of routine preventive measures. Prospective blood product donors who have been to an endemic region within 6 months or treated with malarial prophylaxis within 3 years are not allowed to donate blood products.

The acquired immunodeficiency syndrome (AIDS) epidemic has affected transfusion therapy. In the United States, 3% of AIDS cases have been linked to blood products. In addition, 65% of hemophiliacs in the United States have been exposed to the virus. Voluntary deferment by high-risk groups was encouraged in 1983, and formal screening of all blood products began in 1985. Given that any units that test positive for the human immunodeficiency virus (HIV) antibody are routinely discarded, concern over transmission of the virus centers around the 6- to 8-week "window," during which a donor might be antigen-positive (HIV-infected) but temporarily antibody-negative. It has been estimated that the likelihood of transmitting HIV through blood products is 1:493,000 per unit of blood donated. [1] If a blood recipient's antibody level remains negligible 6 months after transfusion, it is extremely unlikely that the disease will develop. Zidovudine has not been shown to protect patients receiving blood infected with the AIDS virus.

**Directed Donations**

A system of " *directed donations*," a system by which friends or family members may give blood to be transfused to a given individual, has been proposed to answer the concern over the transmission of HIV. Some believe that the blood products derived from a relative or a friend have a lower likelihood of testing positive for an HIV infection. At this time, directed donation systems are in place in some institutions, but the practice has not been widely supported. It is feared that blood products will be less safe because social pressures may result in no self-deferment of high-risk donors and more clerical errors will be made because of the increased complexity of this system. Finally, there is concern that the directed donation plan will disrupt the normal anonymous blood donor system, leaving fewer units available for other needy patients.

**Crystalloid vs Colloid Solutions**

In the case of a hypotensive patient suffering from acute hemorrhage, continued debate surfaces regarding whether it is most appropriate to administer crystalloid or colloid solutions before the institution of blood component therapy. [2] Crystalloid solutions are promoted as being ideal to replace the interstitial fluid deficit that occurs during bleeding. Unfortunately, these balanced salt solutions freely cross capillary membranes,

thus providing less oncotic pressure and less prolonged plasma volume expansion than is desired. Thus, only 10 to 20% of the administered crystalloid solution remains intravascular, perhaps for only 2 hours.

Colloid solutions contain large, oncotically active molecules that remain within the capillary membrane. They are efficient blood volume expanders because fluid deficits can be replaced faster with two to four times less volume than that needed with crystalloid solutions. [3] Unfortunately, colloid solutions cost 20 to 30 times more than a comparable amount of crystalloid solutions.

Three colloid preparations are commercially available. Albumin is manufactured from donor plasma as either a 5% or 25% solution dissolved in normal saline. Volume expansion typically lasts 24 hours. There is a 0.5% incidence of urticaria, fever, or chills when using this fluid. Hetastarch is a synthetic amylopectin available as a 6% solution dissolved in normal saline. It has an osmolality of 310 mOsm and a pH of 5.5. Volume expansion lasts 24 to 36 hours. Minor adverse effects on clotting have been documented. The rate of adverse reactions is the same as that seen with albumin. Dextrans are high-molecular-weight polysaccharides, which have been known to interfere with typing and crossmatching as well as with platelet function.

There are data to support either viewpoint in the crystalloid versus colloid debate. Unfortunately, the information is confusing and frequently conflicting. Although fluid resuscitation can be adequately accomplished with the use of crystalloids, when severe blood loss is replaced with crystalloids alone, marked overexpansion of the extracellular fluid volume occurs. Although colloids typically offer no obvious clinical advantage and it would be imprudent to use them routinely in hemorrhagic fluid resuscitations, they are more efficient plasma volume expanders.

Human studies are now being reported in which the prehospital use of hypertonic saline (4 mL/kg of 7.5% sodium chloride) have proven beneficial in restoring trauma victims' blood pressure and survival compared with conventional isotonic solutions. The addition of dextran to the hypertonic saline seems to add nothing to the positive outcomes.

## USE OF BLOOD PRODUCTS

Blood products are divided into components and fractions. Blood components, such as fresh frozen plasma (FFP), packed RBCs, granulocytes, cryoprecipitate, and platelets, are prepared from a single donor and are separated by physical means and transfused as single units.

The availability of autotransfusion devices in most emergency departments provides an opportunity to preserve blood bank resources that might otherwise be needed. The autotransfused blood harvested from the patient's intrathoracic cavity is fresh, warm, compatible, inexpensive, immediately available, and unlikely to cause a transfusion reaction. Once the blood is collected, it is passed through a filter that removes extraneous debris, and then it is reinfused through a standard IV line. Although controversial, most authorities recommend administering citrate-phosphate-dextrose (CPD) with the whole blood. Potential complications include air embolization,

coagulopathy if large volumes of blood are administered, and sepsis if contaminated blood is disseminated.

Although of limited clinical applicability to emergency transfusions, autologous donations are commonplace. It has been suggested that up to 10% of the blood supply could be provided through this mechanism. Most appropriate applications at this time include elective cardiac, gynecologic, orthopedic, and vascular surgical cases. Benefits of this system include avoidance of exogenous bloodborne disease and sensitization. The individual can donate 1 unit of blood weekly, until 3 days before the surgical need. As blood can be stored up to 35 days, the donations usually begin 5 weeks before they will be needed. The blood donor will require iron supplements and must maintain a hemoglobin >11 g/dL. Table 29-4 lists some characteristics of blood and its components.

**Whole Blood**

Individuals normally have 70 to 80 mL/kg of whole blood. Whole blood provides a source of red cells for oxygenation, proteins for coagulation factors and oncotic pressure, and volume for rapid restoration of hypovolemia. Whole blood is indicated only for massive transfusion or exchange transfusion and usually is appropriately used only in treatment of patients with a decreased RBC oxygen-delivering ability and hypovolemic shock, such as after multiple trauma. Whole blood is *not* the indicated treatment for hypovolemic shock that can be treated effectively with crystalloid (e.g., lactated Ringer's solution, 0.9% sodium chloride) or colloid (e.g., plasma protein, albumin) solutions; it is *not* indicated for correction of thrombocytopenia, replacement of coagulation factors, or treatment of anemia that can be treated with replacement iron, vitamin $B_{12}$ , or folic acid. Most blood banks currently do *not* stock significant quantities of whole blood; instead they substitute packed erythrocytes for indications previously assigned to whole blood.

| TABLE 29-4 -- Characteristics of Blood and Its Components | | | |
| --- | --- | --- | --- |
| **Component** | **Volume** | **Shelf Life** | **Requirements for Transfusion** |
| Whole blood * | 450 mL blood | 21 days at 4° C | Crossmatched |

| | | | |
|---|---|---|---|
| ACD | 63 mL anticoagulant and preservative | | |
| CPD | | | |
| CPD-A | 35-40% hematocrit | 35 days at 4° C | |
| Packed red cells concentrate, washed | 280 mL 70% hematocrit | Same as for whole blood | Crossmatched |
| | 250 mL 70% hematocrit | 1 day at 4° C | Crossmatched |
| Frozen-thawed red cells | 250 mL 70% hematocrit | ? years when frozen, 1 day after thawing | Crossmatched |
| Platelet concentrate | 30 mL $10^{10}$ platelets | 5 days at 22° C | Type-specific if possible, but not essential, not crossmatched |
| Fresh frozen plasma | 200-250 mL | 1 year at - 18° C, 24 hr after thawing | ABO-compatible; random donor, not crossmatched |
| Cryoprecipitate | 10-25 mL per bag 60-120 units of factor VIII | 1 year at - 18° C, 6 hr after thawing | ABO-compatible; random donor, not crossmatched |

| Factor IX or prothrombin concentrate | 25 mL per vial | Check label | None required |
|---|---|---|---|
| Granulocyte concentrate | 400 mL 10$^{10}$ leukocytes | Transfuse within 24 hr at 22° C | Specific donors for each patient, crossmatched |

* ACD, acid-citrate-dextrose; CPD, citrate-phosphate-dextrose; CPD-A, citrate-phosphate-dextrose-adenine.
Special order--few hospitals have facility inhouse.
Use immediately to correct deficiency of coagulation factors.

Whole blood is collected from donors into plastic bags containing 63 mL of citrate-phosphate-dextrose (CPD) anticoagulant and preservative in a total volume of 515 ± 50 mL and resultant hematocrit of 35 to 40%. If >24 hours old, whole blood is essentially devoid of normally functioning platelets and other clotting factors, especially the labile clotting factors V and VIII. In addition, whole blood contains antigenic leukocytes and serum proteins, which may produce allergic reactions (a risk of 1%).

Because blood products are stored for up to 35 days, various "storage lesions" occur. Some blood banks now use ADSOL (adenine, dextrose, saline, mannitol, and water) as a preservative, which increases storage life up to 49 days. Cell metabolism continues to occur while blood is being stored, so a small degree of acidosis commonly develops. However, this acidosis is buffered effectively by the bicarbonate derived from the metabolism of the citrate used as a preservative, assuming normal hepatic function. Even in massive transfusions, acidosis is usually due to the disruption of normal physiologic function rather than to the blood products themselves. During storage, levels of 2,3-diphosphoglyceric acid (2,3-DPG) also decrease. This decrease results in the shift of the oxygen-hemoglobin dissociation curve to the left. The shift is of small clinical significance, however, because the level soon rises and is usually normal in the recipient within 24 hours of infusion. In addition, potassium commonly leaks out of the cells during storage because of a less efficient sodium-potassium adenosine triphosphatase (ATPase)-dependent pump. Fortunately, most of the potassium is either absorbed by the remaining blood cells, excreted by the kidney, or shifted back into the cells owing to the alkalosis produced by metabolism of the citrate in the preservative. Hyperkalemia is clinically relevant only in newborns and patients with renal impairment.

The incidence of transfusion reactions following transfusion with whole blood is approximately 2.5 times greater than the incidence of reactions following transfusion with packed RBCs. [5] Although it is certainly true that patients bleed whole blood, not packed cells, it is often recommended that even acute blood loss be treated with packed cells as opposed to whole blood. [6] One unit of whole blood raises the hematocrit approximately 3%. The plasma of whole blood is no more effective than 5% albumin as

a volume expander.

**Packed Red Blood Cells**

Packed RBCs provide oxygen-carrying capacity and volume expansion. Packed RBCs are prepared by centrifugation and removal of most of the plasma from citrated whole blood. Packed RBCs that have been grouped and have been assayed for Rh factor should be the most common blood component used for treating anemia not amenable to nutritional correction. Hazards of metabolic derangements, donor antibodies, volume overload, and (possibly) hepatitis are lessened with packed RBCs as compared with whole blood. Patients with severe or chronic anemia or heart disease or those who otherwise require fluid restriction can receive packed RBCs more safely than whole blood. Furthermore, to prevent circulatory overload in susceptible patients, a rapid-acting diuretic, such as furosemide or ethacrynic acid, can be administered IV at the beginning of the transfusion. Criteria for transfusion of packed RBCs vary. A hemoglobin level <10 g/dL is one criterion commonly suggested for transfusion

prior to surgery. The National Institutes of Health suggest that prophylactic transfusion should not be done on anemic patients with a hemoglobin >7 g/dL (hematocrit 21%). Healthy individuals sustaining acute blood loss may have no significant physiologic impairment with hemoglobin levels as low as 6 to 8 g/dL (hematocrit, 18 to 24%). The patient with circulatory shock and a hemoglobin concentration of 8 g/dL or greater may not benefit from a transfusion if volume-resuscitation has already been undertaken. [7]

One unit of packed RBCs contains the same red cell mass as 1 unit of whole blood at approximately half the volume and twice the hematocrit (70 to 80%). One unit of packed RBCs raises the hematocrit approximately 3% in an adult or increases the hemoglobin level of a 70-kg individual by 1 g/dL. In children, there is an approximate rise in hematocrit of 1% for each mL/kg of packed cells. For example, if 5 mL/kg of packed RBCs is transfused, the hematocrit will rise by approximately 5%. Actual changes are dependent on the state of hydration and the rate of bleeding.

When washed to remove leukocytes, platelets, microaggregates, and plasma proteins, packed RBC transfusions cause fewer transfusion reactions than do whole blood transfusions. RBCs are not routinely washed before transfusion, but washing reduces the titer of anti-A and anti-B, permitting safer transfusion of type O packed RBCs in non-O recipients. Washing does not totally eliminate the risk of hepatitis. Washed RBCs are prepared in the blood bank by centrifugation, filtration, or use of sedimenting agents or by washing the unit of whole blood or packed RBCs.

Frozen deglycerolized RBCs likewise are free of platelets, plasma, and white blood cells, having been washed after an indefinite period of frozen storage in glycerol. Frozen RBCs and fresh RBCs function similarly; frozen RBCs provide normal levels of 2,3-DPG. Washed or frozen preparations should be given to patients who have had febrile (nonhemolytic) reactions to previous transfusions as a result of leukocyte antibodies or IgA sensitization. Blood bank procedures require that these be prepared to order, with routine crossmatching. Considerable delay (6 hours) may occur if the

transfusion service does not have the capability of washing RBCs.

Packed RBCs contain less sodium, potassium, ammonia, citrate, and antigenic protein and fewer hydrogen ions than does whole blood. This may offer an advantage in patients with reduced cardiovascular, renal, or hepatic function. The rate of urticaria is still relatively high at 1 to 3% of transfusions, but the incidence of adverse reactions to packed cells is approximately one third that noted with whole blood.

Many physicians use packed RBCs during surgery and for replacement treatment of acute blood loss of any cause. As is true of whole blood, packed RBCs can be stored up to 21 days by law, although newer preservatives may allow 49-day storage. Red cell viability decreases approximately 1% per day.

**Fresh Frozen Plasma**

Fresh frozen plasma should be given to patients with a hereditary or acquired deficiency of coagulation factors, provided that a preparation of the specific deficient factor is not available. Each unit of FFP has a volume of approximately 200 to 250 mL and is prepared by freezing the plasma separated from RBCs and platelets of single-donor whole blood, and stored at 18 °C or below within 8 hours of collection. Plasma should be compatible in terms of the recipient's ABO group. Rh compatibility is not considered essential. [8]

Fresh frozen plasma contains all soluble coagulation factors of the intrinsic and extrinsic clotting systems, including the labile factors V and VIII. Fresh frozen plasma also contains fibrinogen, although not as much as does cryoprecipitate. Fresh frozen plasma has a shelf life of up to 1 year, and plasma stored for 3 months retains approximately 60% of the normal factor VIII activity. Fresh frozen plasma contains no platelets.

Fresh frozen plasma is indicated for the clotting factor deficiencies resulting from the diluting effect of massive blood replacement. However, pathologic hemorrhage following massive transfusions is often caused by thrombocytopenia rather than by a depletion of clotting factors. One unit of FFP per 5 to 6 units of packed cells or whole blood is a reasonable replacement formula if specific clotting tests are not rapidly available, but plasma replacement is best dictated by evaluation of prothrombin time (PT) and partial thromboplastin time (PTT). Fresh frozen plasma is indicated for rapid reversal of serious acute bleeding from warfarin (Coumadin) anticoagulants or for prophylaxis prior to surgery or an invasive procedure. In an emergency situation, 5 to 10 mL/kg of FFP will effect a rapid reversal of the vitamin K-dependent factors II, VII, IX, and X. As a rough guide, 1 unit of FFP increases all coagulation factor levels by 2 to 3% in the average-sized adult. In *life-threatening* hemorrhage from warfarin excess, factor IX concentrate (Konyne 80, Proplex, Mononine) may be used, but such therapy should not be routine because of the high incidence of hepatitis and the possibility of thrombosis with these products.

Fresh frozen plasma may be valuable in patients with other clotting abnormalities, such as a congenital deficiency of factor II, V, VII, X, XI, or XIII, von Willebrand syndrome, hemophilia A (factor VIII deficiency) and hemophilia B (factor IX deficiency), or

hypofibrinogenemia; however, the effectiveness is limited in severe clotting abnormalities because of the large volume that is generally required. For example, FFP may be successful in the treatment of hemarthrosis or other minor bleeding tendencies in hemophilia, but specific factor replacement is preferred. Fresh frozen plasma is also used to treat the acquired deficiency of multiple factors such as that seen in severe liver disease, disseminated intravascular coagulation, or vitamin K depletion, and for plasma exchange in thrombotic thrombocytopenic purpura or hemolytic uremic syndrome. Fresh frozen plasma should not be used for volume expansion or to enhance wound healing.

Reactions to FFP include fever, chills, allergic responses, HIV infection, and a risk of hepatitis that is similar to the risk with whole blood. Fresh frozen plasma should be infused rapidly and given immediately after thawing because of the rapid loss of labile clotting factors.

The usual starting dose is 2 bags of FFP if the PT is >1.5 times normal or the activated PTT (aPTT) is >1.5 times the top normal value. If the PT is <22 seconds or the aPTT is in the 55 to 70 second range, one bag of FFP may be sufficient to bring the deficit into the hemostasis range (Table 29-5) . Each 5 to 6 units of platelets contain the equivalent of unit of FFP, so concomitant platelet infusions may lower FFP requirements.

| TABLE 29-5 -- Transfusion of Blood Products | | | |
|---|---|---|---|
| **Blood Product** | **Waiting Time to Receive in Emergency Department** | **Initial Amount to Transfuse** | **Expected Response in 70-kg Adult** |

| | | | |
|---|---|---|---|
| Un-crossmatched Rh+ or Rh- RBCs | 5 min | 2-10 units, 10 to 20 mL/kg/ hr or as needed based on clinical condition | Stabilize patient in shock |
| Un-crossmatched type-specific whole blood | 15 min | | Change in hemoglobin/hematocrit depends on hydration and rate of bleeding |
| Typed and screened whole blood | 25 min | | Approximate rise of 1 g dL hemoglobin per unit |
| Crossmatched whole blood | 1¼ hr | | |
| Packed RBCs | 1½ hr | | Each unit raises hematocrit 2-3% |
| Frozen RBCS | 4-6 hr (if not prepared inhouse) | | In children, each mL/kg of packed cells raises hematocrit by 1% |
| Platelet concentrate | 5 min if available | 1 unit per 10 kg, usually 6 to 10 units per transfusion in an adult | Rise of 5000 to 10,000 platelets per mm3 per unit; 6 units usually sufficient to stop bleeding |
| Cryoprecipitate | 20 min | 1-2 bags per 10 kg (7-15 bags) 10-min push, or 20-50 units/kg | Rise of 3% in factor VIII level per bag (40-100% activity desired) |

| Factor IX or prothrombin concentrate | Immediately available (reconstituted powder) | 10-50 units/kg | 30-100% rise in factor IX activity |
|---|---|---|---|
| Fresh frozen plasma | 40 min | 1 bag per 7 kg (4-10 bags for adult) 10-min push, *3-10 mL/kg, depending on clinical condition | Correction in coagulation status; 1 unit raises all coagulation factors by 2-3% in average-sized adult |

Also consider thrombocytopenia as a cause of bleeding from massive transfusion.
* Administer 1 bag per 4 to 6 units of blood transfused to replace diluted and inactivated coagulation factors.

**Cryoprecipitate**

Cryoprecipitate is used specifically to correct a deficiency of coagulation factor VIII (in hemophilia A and in von Willebrand syndrome), factor XIII, or fibrinogen. The precipitate is prepared from single-donor plasma by gradual thawing of rapidly frozen plasma, which yields an undissolved protein that is collected and stored at very low temperatures. Cryoprecipitate is a plasma product and as such requires ABO and Rh compatibility, but crossmatching is not necessary.

Cryoprecipitate contains approximately 30 to 50% of the original plasma content of factors VIII and XIII and fibrinogen. Each 15- to 25-mL bag of cryoprecipitate contains 60 to 120 units of factor VIII, 125 to 250 mg of fibrinogen, and an unknown amount of von Willebrand factor. Cryoprecipitate is of no value in the treatment of factor IX deficiency (hemophilia B).

Once spontaneous bleeding has occurred in hemophilia or von Willebrand syndrome, it will usually *not stop until the deficient factor is replaced*. It is best to treat early to prevent minor bleeding from developing into a significant hemorrhage. The goal of therapy is to achieve at least 50% of normal factor VIII activity. In spontaneous intracranial hemorrhage, one should seek 100% activity. The amount of cryoprecipitate required to correct coagulation defects ranges from 10 to 20 units/kg for minor bleeding, such as hemarthrosis, to 50 units/kg for bleeding control in surgery or trauma, but specific replacement should be guided by laboratory assay of factor VIII activity. One bag of cryoprecipitate per 5 kg of body weight will raise the recipient's factor VIII level to approximately 50% of normal. The half-life of factor VIII in plasma is 8 to 12 hours. Mild deficiencies of factor VIII are considered to exist at 10 to 30% of normal, and severe deficiencies exist at <3% of normal activity. Many patients know their level of factor VIII,

and such levels remain relatively constant.

Rarely, cryoprecipitate may be required to correct significant hypofibrinogenemia (<100 mg/dL). Fresh frozen plasma may also be used to treat mild degrees of hypofibrinogenemia.

**Factor VIII Concentrate**

Factor VIII concentrate is a product for the treatment of classic hemophilia A. It is derived from a large donor pool and can be stored for up to 2 years in a home refrigerator. The product is significantly more concentrated than cryoprecipitate or FFP. The known factor activity is listed on every bottle. Administration of 1 unit per kg of body weight should increase the factor VIII activity by 2%. Minor episodes of bleeding are usually treated with 10 to 20 units/kg, whereas major episodes are treated with 20 to 30 units/kg, with a

repeat dose 12 hours later. Antibodies develop in up to 15% of factor VIII recipients. Various techniques have been used to overcome this problem. Administration of massive doses of factor VIII has been shown to be somewhat beneficial in overwhelming the endogenous antibody response. In addition, immunoadsorbent techniques to remove the antibody have met with some guarded success. The general use of immunosuppressives and plasmapheresis has had limited success. Activated prothrombin complex has been effective, but concern over the cost of preparation, the significant hepatitis risk, and the thrombogenicity associated with its use limits its application.

Because factor VIII concentrate is derived from large donor pools, the likelihood of transmission of hepatitis and HIV infection is higher. Different forms of chemical treatments have been attempted to minimize this threat. These techniques include heat treatment, pasteurization, use of organic solvents and detergents, and immunoaffinity chromatography. Since the gene for factor VIII production was discovered in 1984, research into recombinant genetics has been aimed at providing a safer product that theoretically will be more readily available and less expensive to produce. Two recombinant-DNA derived factor VIII preparations (Recombinate, Kogenate) were approved by the FDA in 1993. Although these genetically engineered products have hemostatic activity equivalent to plasma-derived factor VIII and are thought to be free of viral contaminants, they remain much more costly than other products. [9]

A synthetic analogue of pituitary vasopressin, 1-deamino-(8-D-arginine)-vasopressin (DDAVP), has been found to stimulate the endogenous production of factor VIII in a subset of mild hemophiliacs. The exact mechanism is unknown, but treatment with 0.3 mg/kg IV over 15 minutes has been recommended when avoidance of the inherent risks of the factor VIII concentrate is desired.

**Factor IX Concentrate (Prothrombin Complex)**

Prothrombin complex concentrate, or factor IX concentrate (Konyne or Proplex), is

prepared from pooled human plasma and is available as a lyophilized powder. Factor IX concentrate contains the liver-synthesized, vitamin K-dependent factors: II (prothrombin), VII, IX, and X. The actual factor IX activity of each vial is stated on the label. Each vial is reconstituted to a volume of 25 mL and contains approximately 500 units of factor IX, 300 units of factors VII and X, and 200 units of factor II. The use of this product carries a very high risk of hepatitis transmission (almost 100%); because of this, it is rarely used. The risk of HIV infection is analogous to that seen with the use of factor VIII concentrate. Post-treatment hyperthrombosis may also occur.

Factor IX concentrate is used almost exclusively in the treatment of hemophilia B, because cryoprecipitate is effective only for the treatment of hemophilia A (factor VIII deficiency). Patients with hemophilia should always be asked which deficiency they manifest, because the treatment of each type is different. Although factor VIII deficiency is much more common, the routine treatment of all patients with "hemophilia" with cryoprecipitate is not warranted. Factor IX concentrate may theoretically be used instead of FFP in the rare instance in which volume must be kept at a minimum. The use of prothrombin complex is also warranted when there is a possibility of *life-threatening* hemorrhage, such as intracranial bleeding, in patients with *warfarin-induced* hemorrhage. Vitamin K and FFP, however, are definitely preferred in the noncritically ill patient with warfarin-induced bleeding. A new monoclonal antibody purified factor IX preparation, safe from the risks of hepatitis and thrombogenicity, is now available.

In hemophilia B, the aim of therapy is to achieve 20 to 30% of normal values of factor IX. Higher levels are desired for the treatment of intracranial bleeding. Most patients know the level of their deficiency, and the deficiency remains relatively constant. Treatment of factor IX-deficient patients with 15 to 30 units of factor IX concentrate per kilogram of body weight, once or twice a day, usually results in normal hemostasis, but individual responses to therapy may vary. Minor bleeding (soft tissue, joints) may be controlled with 10 to 20 units/kg of body weight. It is a common error to assume that a minor spontaneous bleeding episode will be self-limited in patients with either form of hemophilia. Once spontaneous bleeding occurs, however, it rarely stops spontaneously, and treatment with replacement factors is necessary.

**Platelet Concentrates**

Platelet concentrates are prepared by rapid centrifugation of platelet-rich plasma, which is obtained by slow centrifugation of freshly collected whole blood to separate the RBCs. Platelets are obtained by single-donor apheresis or from random donor whole blood units. HLA-matched platelets may be used when patients develop HLA antibodies from repeated random donor platelet transfusions. Platelet concentrates contain most of the platelets from 1 unit of blood in 30 to 50 mL of plasma; they are given to raise a patient's platelet count and to correct bleeding from thrombocytopenia. One unit (pack) of platelets per 7 kg of body weight will raise the platelet count by 50,000/mm3 in the absence of antibodies; therefore, 1 unit of platelet concentrate raises the platelet count by 5000 to 10,000/mm3 . The usual adult dose given is 6 to 10 units of platelet concentrate, depending on the clinical condition. Assuming a zero platelet level, 6 units given to a normal-sized adult should increase the platelet count to >50,000 per mm3 . If

there is no evidence of platelet consumption, this transfusion should be adequate for 3 to 5 days. In cases of severe platelet consumption the transfusion may be required every 6 to 24 hours. Some hospital blood banks prepare platelet concentrates regularly; in some cities a central blood bank service, such as the American Red Cross, prepares platelet concentrates regularly and delivers units on an "as-needed" basis within 1 to 2 hours of the request. Platelet concentrates are viable for 5 days when kept at *room temperature* and gently agitated at intermittent periods or when kept in motion. They should not be refrigerated.

This issue of prophylactic platelet transfusion remains controversial. Spontaneous bleeding rarely occurs if the platelet count is above 10,000 to 20,000/mm3 . Even in the event of surgery or trauma, excessive bleeding is uncommon in patients whose platelet count exceeds 50,000/mm3 . It is generally recommended that active hemorrhage be treated with platelet transfusion if the platelet count is below 50,000/mm3 , but prophylactic transfusion may be safely withheld until the platelet count is <20,000/mm3 . Patients with idiopathic thrombocytopenic purpura (ITP) should not

receive platelets prophylactically, but they may be transfused if life-threatening bleeding occurs.

Crossmatching is unnecessary for platelet transfusion, but the donor and the recipient should be ABO- and Rh-compatible. Note that platelet concentrates contain enough RBCs to sensitize an Rh-negative individual. There may be a diluting effect to the platelet count that results in thrombocytopenia with massive blood transfusions. When >8 to 10 units of blood is transfused, the platelet count must be routinely evaluated, and platelets must be replaced accordingly. Clinically significant platelet depletion rarely occurs if <15 units of blood (or 1.5 to 2 times blood volume) have been transfused.

Each 5 to 6 units of platelets will contain 250 to 350 mL of plasma (about 1 bag of FFP), which includes coagulation factors that may reduce the requirements of FFP. Platelets may be infused rapidly (1 unit/10 minutes), using specialized platelet filters.

**Granulocyte Transfusions**

Granulocyte transfusions are given in those unique instances in which a severely neutropenic patient has a suspected or proven bacterial infection that does not respond to appropriate treatment. They are rarely given in an emergency department. White blood cell transfusions require prior arrangements with a large blood bank service that has the capabilities of collecting granulocytes from a suitable donor; the collection procedure takes 4 to 6 hours on a continuous-flow cell separator. Transfusions need to be repeated frequently (every 12 hours) to provide a sufficient number of white blood cells to help the patient.

**Blood Products for Jehovah's Witnesses**

There are more than 1.5 million Jehovah's Witnesses in the United States. Based on the religious belief that the Bible prohibits blood or blood product transfusion (Acts

15:28-29), members of this religion do not accept transfusions of whole blood, packed cells, white blood cells, platelets, or plasma or autotransfusion of predeposited blood. Some may permit infusion of albumin, clotting factor solutions, or dextran or other plasma expanders and intraoperative autotransfusion. [10] Although no guidelines for administration of blood products to Jehovah's Witnesses are absolute, certain recommendations can be made. Even though a transfusion may be necessary to save a patient's life and would otherwise be considered standard care, the administration of blood and/or blood products in the face of refusal after informed consent can be legally considered as battery or a violation of a patient's right to control what is done to his or her body. In the awake and otherwise competent adult, courts have ruled that physicians cannot be held liable if they comply with a patient's directive and withhold life-saving blood administration following specific and detailed informed consent of the consequences of such an omission of treatment. The issue becomes clouded when patients are incompetent, unconscious (most Jehovah's witnesses carry cards informing medical personnel of their religious beliefs), or minors.

In the absence of specific directives to the contrary it is prudent to administer blood products to patients who are unconscious or are judged to be incompetent adults or are minors. Although case law often upholds the patient's wishes, actual damages against physicians are difficult to document in the United States. When done under documented life-threatening circumstances, significant physician liability would be extremely unusual. Pregnant females and significant providers for dependents have been deemed appropriate recipients of blood products against their wishes. Explicit documentation of the intent of the physician to preserve life coupled with an accurate description of the discussion of the issue with the patient or the family and a clarification of the patient's mental capacity is mandatory. Furthermore, emergency legal assistance (such as court orders, appointment of a temporary guardian) should be sought immediately with rapid judicial resolution. Various clinical techniques to maximize oxygen delivery and minimize oxygen consumption should be used. Examples include limited blood draws, the use of erythropoietin and nutritional support, hypothermia, volume expansion, sedation, and oxygen.

## ADMINISTRATION OF BLOOD COMPONENTS

When it has been decided that a patient needs a transfusion and the patient's condition is stable enough, the physician should question the patient or the patient's relatives concerning any previous transfusion reactions and whether the patient abides by any religious prohibitions to transfusions. A tube of blood (approximately 2 mL for every unit of blood product to be crossmatched) should be drawn from the patient and put into a red-topped, non-anticoagulated tube. The tube must *not* contain a serum separator gel. The label should be signed by the physician. This identifying signature will be used in the blood bank's crossmatching procedures.

### Emergency Transfusion

In an emergency or life-threatening situation, three alternatives to fully crossmatched blood exist. The preferred substitute is type-specific blood with an abbreviated crossmatch. The abbreviated crossmatch includes ABO and Rh compatibility. In

addition, the recipient's serum is screened for unexpected antibodies, and an immediate "spin" crossmatch is performed at room temperature. This abbreviated crossmatch requires approximately 30 minutes, and many institutions are now using this procedure as their standard crossmatch for most patients. The safety and utility of the type-specific abbreviated crossmatch have been demonstrated repeatedly, and transfusion reactions should occur only rarely. [11]

The second preference for an alternative to fully crossmatched blood is type-specific blood that is only ABO- and Rh-compatible, without screen or immediate spin crossmatch. The patient's ABO group and Rh factor can be determined within 2 minutes, and, in an emergency, typing of the blood group and the Rh factor is all that is necessary before transfusion. Type-specific blood that is not crossmatched has been given in numerous military and civilian series without serious consequences. While the type-specific blood is being transfused, the antibody screen and the crossmatch are carried out in the laboratory; the transfusion should be stopped if an incompatibility is found.

Ideally, type-specific blood should be similar in Rh factor as well as in ABO group; however, blood with the opposite Rh factor may be used in an extreme emergency or in

times of disaster or blood shortage. The patient may develop sensitization to the Rh factor. [12] This may affect a subsequent pregnancy if an Rh-negative woman is given Rh-positive type-specific blood. A male patient may likewise be sensitized to subsequent Rh-incompatible transfusions.

The third preference for an alternative to fully crossmatched blood for an emergency transfusion is group O blood. [13] In general, type-specific blood is preferable to group O blood. There is rarely a situation in which a few minutes cannot safely be expended to allow the blood bank to release type-specific blood. Nevertheless, exceptions may occur, in which case type O blood may be required. Such exceptions would include a trauma victim or a patient with a ruptured aneurysm or ruptured ectopic pregnancy who has not responded to crystalloid resuscitation in the field.

When type and Rh determination creates an unacceptable delay in transfusion, group O blood (either as whole blood or as packed cells) is transfused. Packed cells are preferred over whole blood. Group O negative *whole* blood was in the past designated the "universal donor" blood, because a recipient's naturally occurring antibodies (anti-A and anti-B) will not react with donor group O RBCs. Nonetheless, some donor serum may have a high titer of naturally occurring anti-A and anti-B antibodies capable of hemolyzing the recipient's (patient's) RBCs if large quantities of blood are transfused. True universal donor blood is low in anti-A and anti-B titer. Because group O donors are not regularly screened for unsafe levels of anti-A and anti-B titers, the use of even small amounts of group O *whole blood* that is not crossmatched is potentially dangerous. The significance of varying titers of anti-A and anti-B antibodies in the donor whole blood may be essentially eliminated if *packed cells* are used instead of whole blood. Other RBC antigens on type O RBCs may sensitize the patient or may cause antibody production, complicating future crossmatching or possibly causing future hemolytic

transfusion reactions.

Approximately 25% of patients receiving a transfusion of 5 or more units of type O whole blood develop hyperbilirubinemia suggestive of a minor hemolytic reaction. Large amounts of group O whole blood may cause the patient to acquire significant amounts of anti-A and anti-B antibodies that have been passively transfused; hemolysis of RBCs may then occur when the recipient's original blood group is subsequently transfused. In a resuscitation, one should continue to use group O blood if large amounts (i.e., >2 units) of *whole blood* have already been given.

One may transfuse both Rh-positive and Rh-negative group O packed cells in patients who are in critical condition. It is a common *misconception* that patients who are Rh-negative will have an immediate transfusion reaction if given Rh-positive blood. There is no particular advantage in the Rh factor determination because preformed, naturally occurring anti-Rh antibodies do not exist. Theoretically, individuals who are Rh-negative may become sensitized either through pregnancy or by previous transfusions, resulting in a delayed hemolytic transfusion reaction if Rh-positive blood is transfused. However, this scenario is very rare and is of no great clinical significance when compared with life-threatening blood loss. Many advise the routine use of *O Rh-positive* packed cells in all patients for whom the Rh factor has not been determined, except in females of childbearing age, for whom future Rh sensitization may be an important consideration. Once resuscitated with Rh-positive blood, patients may receive their own type without a problem. Because individuals with O Rh-negative blood represent only 15% of the population and the blood may be in short supply, it is reasonable to save O Rh-negative blood for Rh-negative females of childbearing potential and to use *group O Rh-positive packed cells routinely as the first choice for emergency transfusions*. In a study of emergency blood needs, Schmidt and colleagues reported 601 units of Rh-positive type O blood transfused to 193 patients, including 8 Rh-negative women, before blood type was determined. No acute hemolytic reaction occurred, and no women were sensitized. Rh immune globulin prophylaxis is recommended only for Rh-negative women with childbearing potential receiving Rh-positive blood.

If non-crossmatched blood is transfused, the laboratory should receive a plain (without a serum separator) red-top tube of venous blood as soon as possible to begin a formal crossmatch procedure. Brickman and coworkers have demonstrated that bone marrow aspirates obtained by an intraosseous needle can be used for crossmatching. [14]

Rh immune prophylaxis with human immune globulins (RhoGAM) is indicated for Rh-negative pregnant women who may be bearing Rh-positive children and may have fetomaternal transplacental hemorrhage. These events include bleeding in early pregnancy, such as spontaneous or elective abortion, ectopic pregnancy, and other potential causes of antepartum hemorrhage such as trauma. The indications for Rh immunoglobulin in *threatened abortions* is less clear but is advocated by some. The product suppresses the immune response of Rh-negative women to Rh-positive RBCs, and it is effective when given up to 72 hours after exposure to fetal erythrocytes. Dosing of Rh immunoglobulin is 50 mug IM for first-trimester bleeding and 300 mug IM for later bleeding. [15] In the setting of significant fetal-maternal transfusion (usually only in the

third trimester), doses may be increased. Rh immunoglobulin is prepared in the blood bank and the correct dose is suggested on an individual basis, following confirmation of Rh status, evidence of prior sensitization, and testing for fetal erythrocytes in the mother's blood.

## Transfusion Coagulopathy

Within the past 10 years it has been appreciated that pathologic hemostasis occurs following massive blood transfusions. [16] [17] [18] The exact cause of the transfusion coagulopathy is poorly defined and poorly understood. Although such abnormalities rarely develop within the time frame of the initial resuscitation in the emergency department, an understanding of the problem leads to a more intelligent approach to transfusion practices and the anticipation of potential problems. The term *massive transfusion* is loosely defined but is usually considered to be the transfusion of >10 units of blood to an adult (equivalent to one blood volume) within 24 hours. In patients who are given a transfusion that is equal to two blood volumes, only approximately 10% of the original elements remain. Considering the significant alteration in blood and blood products that occurs during storage, one can readily appreciate the underlying problem associated with such massive transfusions. The development of transfusion coagulopathy is multifactorial and in large part is related to tissue injury and duration of shock. [19]

Abnormalities in platelets and plasma clotting factors also play a role.

### Platelets

Transfusion coagulopathy is related partly to a diluting effect of the transfusion of blood deficient in platelets. Disseminated intravascular coagulopathy plays a secondary role in post-transfusion bleeding.

Banked whole blood and packed cells are devoid of functioning platelets. Dilutional thrombocytopenia is a well-recognized complication of massive transfusion, and a platelet count should be obtained routinely if >5 units of blood is transfused. As a general guideline, platelet therapy should be considered after the first 10 units of blood has been given, although the most useful parameter for estimating the need for platelet transfusions is the platelet count.

### Plasma Clotting Factors

Factors V and VIII are labile in stored blood and absent in packed cells. Fibrinogen is relatively stable in stored blood but is absent in packed cells. A deficiency of most clotting factors, especially factors V and VIII and fibrinogen, occurs with massive transfusions. This deficiency probably occurs on a "washout" (i.e., dilutional) basis, although the dynamics are poorly understood. The replacement of these factors may be required. Specific assays for the individual factors are available, but it is more practical to measure aPTT, PT, and fibrinogen levels. Fresh frozen plasma has been used to correct clotting factor abnormalities secondary to dilution from massive transfusions, but

its effectiveness has not been firmly established. Cryoprecipitate has also been used to replace factor VIII and fibrinogen, but it is rarely required, because FFP contains some fibrinogen. Fresh frozen plasma should be infused to correct the coagulopathy as indicated by clotting studies, but as a general guide, 1 to 2 units of FFP may be given empirically for each 5 to 6 units of blood in the massively traumatized or bleeding patient. Cryoprecipitate may be required if fibrinogen levels fall below 100 mg/dL and are not adequately supplemented with FFP.

## ORDERING OF BLOOD

Ordering a type and crossmatch procedure on a blood product implies that the decision has already been made to administer a transfusion. A "type and hold" or "type and screen" (no crossmatch) request alerts the blood bank to the *possibility* that a blood product will be required for the patient, so appropriate units can be acquired and kept on hand. A type and crossmatch procedure takes 45 minutes and restricts a unit of blood to a specific patient. This limits a valuable resource and should not be requested lightly. In the emergency department, a crossmatch procedure should be requested for a blood product only if the adult patient (1) manifests shock, (2) has *symptomatic* anemia (usually associated with a hemoglobin <10 g/dL) in the emergency department, (3) has a documented loss of 1000 mL of blood, or (4) requires a blood-losing operation immediately (e.g., thoracotomy). [20] A type and hold can safely be requested for all other situations in which a blood transfusion is considered possible during the patient's care; a desirable ratio of units crossmatched to units transfused can thus be achieved.

The number of units to be requested for a crossmatch procedure is determined by the size of the patient, the response of the patient to the injury and subsequent emergency treatment, and the presence of ongoing blood losses (e.g., arterial or massive gastrointestinal bleeding). In the majority of fatalities from massive hemorrhage, the patients die from hypovolemia rather than from lack of oxygen-carrying capacity. Specific guidelines for the administration of blood components are given in Table 29-5 .

Red blood cell preparations for transfusion are not routinely tested for the presence of sickle hemoglobin. Donors with sickle trait are not excluded, and blood with sickle trait can be safely given to almost every patient, because occlusion of blood flow caused by intravascular sickling would occur only in extreme conditions of acidity, hypoxia, or hypothermia that are unlikely to be compatible with life. Nonetheless, when transfusion is being performed in infants and patients with known sickle cell anemia, the blood bank should be alerted, and a "sickle prep" should be requested for donor blood to avoid the infusion of sickle-trait blood into such patients. Rare instances have occurred in which blood from a donor with a mild variant, such as SSC disease, caused massive intravascular sickling and death in a sick, hypoxic, acidotic infant. [21]

### Blood Request Forms

The most important part of ordering blood components for a patient is proper identification of the patient and the intended unit of blood. Transfusion of an incorrect unit is a potentially fatal error. *Most transfusion mistakes are clerical errors.* Several identification systems have been established to minimize the risk of improper

transfusions (Fig. 29-1) (Figure Not Available) . Just before administering the blood, the nurse or physician checks the identity of the numbered labels. In addition, the blood bank laboratory slip should identify the patient by name and number and should also contain the identification number of the unit of blood. Because most serious transfusion reactions are due to misidentification issues, one cannot be overcautious in adhering to these identification procedures (Fig. 29-2) (Figure Not Available) .

Usual procedures require a separate *blood bank request form* for each unit of RBCs or whole blood that is ordered. A number of units of FFP, cryoprecipitate, and platelet concentrates may be ordered on one form with proper identification (depending on individual blood bank procedures). When the blood bank indicates that the units ordered are ready, the person picking up the blood, along with the blood bank technician, checks the notation on the *blood release form (transfusion form)* to verify the identity of the patient (name, hospital number) and to ensure that the blood unit has been prepared for that patient (blood group and type, unit number). Immediately before administering the blood to the patient, the nurse or physician should check the release form, blood unit, and patient tag for identity as well as for the expiration date of the unit (Fig. 29-3) (Figure Not Available)

## INTRAVENOUS ADMINISTRATION

One should not open the unit of blood until and unless a free-flowing IV access line has been established in a large-bore vein. A 14-ga IV catheter is preferred, both to minimize hemolysis and to ensure rapid infusion of fluid for the treatment of hypovolemia or hypotension. When large amounts of blood must be given rapidly, administration by means of a high-flow infusion system is preferred. Standard central venous pressure lines are generally too small for adequate volume resuscitation in patients whose condition is critical. Likewise, the purpose of a large-bore infusion line is defeated if blood is piggybacked with an 18- to 20-ga needle through a side port in the infusion tubing. For an elective transfusion, however, blood may be given through a smaller needle. No significant hemolysis occurs when small-gauge (21-, 23-, 25-, and 27-ga) short needles are used for transfusion of fresh blood or packed cells in infants and children and when the maximum rate of infusion is <100 mL/hour. [22] For rapid infusion, however, the blood administration tubing is connected directly to the infusion catheter. The infusion site should be monitored for infiltration, infection, or local reactions. Antiseptic technique is essential (Figs. 29-4 (Figure Not Available) through 29-8 (Figure Not Available) ).

If the patient already has a suitable IV line in place, a solution of 0.9% normal saline only should be used to flush the system before administering the blood. Other IV fluids are *not* to be used because of the risks of hemolysis or aggregation (with 5% dextrose in water) or clotting (with lactated Ringer's solution). [23] No medications can be placed into the unit of blood or added to the infusion line for the same reasons.

### Filters

All blood and blood products should be infused only through an appropriate filter, such as those supplied in-line in the blood administration tubing sets. In the past, filtration

was required merely to keep the IV line from becoming blocked by clots, but the adverse consequences to the patient that result from infusing unfiltered blood products have now been recognized. Debris consisting of clots and aggregates of fibrin, WBCs, platelets, and intertwined RBCs (ranging in size from 15 to 200 mum) will accumulate progressively during storage of the blood unit from the first day of collection. The usual filter, made of a single layer of plastic with multiple 170-mum pores, traps larger particles and still allows for the rapid infusion of blood for 2 to 3 units before flow is greatly obstructed. Purified *components* of blood plasma

**Figure 29-8** (Figure Not Available) After the plastic tubing has been primed with saline, the blood flows through into the patient. *(Courtesy of Fenwal Laboratories, Deerfield, Ill.)*

can be safely administered through a filter with pores as fine as 5 mum.

It has been suggested that microaggregates of debris, which could pass through a 170-mum filter, may in part contribute to the syndrome of "shock lung" seen after transfusions of many units of blood in patients suffering from severe trauma and hemorrhage. Some practitioners therefore recommend the use of a microaggregate blood infusion filter with a mesh pore size of 40 mum (Fig. 29-9) (Figure Not Available) when multiple units of blood are administered to a trauma victim, to a patient with compromised pulmonary function, or to a neonate. Microaggregate filters tend to become blocked, impeding the rate of infusion more quickly, and are not commonly required in the emergency setting. In addition, whether the infusion of microaggregates (between 40 and 170 mum in size) is in fact harmful is still an unsettled issue. [24] Standard filters should be replaced after 2 to 3 units of blood product have been administered; most microaggregate filters should be changed after each unit. It is generally agreed that a significant number of platelets is removed by microaggregate filters, and some advise against using these filters when platelet packs are infused. Others believe that although platelets are removed with the microaggregate filters, the trapped platelets can be removed with saline flush without any significant loss. [25] Table 29-6 lists some available in-line filters.

**Rate of Infusion**

One unit of whole blood can safely be administered to a hypotensive patient at a rate of 20 mL/kg/hour. In the setting

**Figure 29-9** (Figure Not Available) Administration of blood through a microaggregate filter attached between the unit of blood and the hard plastic spike of the administration set. *(Courtesy of Fenwal Laboratories, Deerfield, Ill.)*

of hypovolemic shock and continued hemorrhage, there is no limit to the transfusion rate, and multiple units may be transfused simultaneously, even under pressure. In the stable patient, 1 unit of *whole blood* (500 mL) should be administered over approximately a 2-hour period (3 to 4 mL/kg/hour). After this time, RBCs begin to lose metabolic activity. In addition, the unit of blood, which is an excellent culture medium, is likely to become contaminated if bacteria and fungi are allowed to grow at room temperature. Packed cells should be given at approximately the same rate; plasma

products may be given more rapidly. In a patient with a healthy cardiovascular system, one should administer FFP more rapidly (about 15 to 20 minutes/unit) to correct coagulation deficits, because the coagulant activity begins to deteriorate rapidly after 20 to 30 minutes of thawing. In patients with severe anemia and congestive heart failure, a rapidly acting diuretic, such as furosemide, can be given (0.5 mg/kg IV) at the onset of transfusion to obviate circulatory overload.

If a transfusion of blood must be interrupted or delayed for some reason, the remainder of the blood unit should be returned to the blood bank. More convenient refrigerators in the emergency department or on the hospital unit *should not* be used to store blood products unless they are temperature-controlled or continuously monitored and alarmed.

Patients who are in hemorrhagic shock can receive blood through 2 large-bore catheters at different sites. Usually gravity provides a sufficient pressure gradient if the unit is raised higher above the patient to increase the rate of infusion when the clamps are wide open. If a pressure pump is used (Figs. 29-10 (Figure Not Available) and 29-11) (Figure Not Available) , the infusion can be more rapid. [26] A standard sphygmomanometer cuff should never be wrapped around a unit of blood to create increased infusion pressure, because the nonuniform application of pressure could burst the plastic bag containing the blood component.

One can dilute packed RBCs with *normal saline* (0.9% and without dextrose) before infusion simply by opening the clamps on the upper tubes of the Y infusion set and leaving the lower (recipient end) clamps closed. Although it is generally agreed (and recommended by the editors) that Ringer's lactate solution should never be mixed with blood because of possible clot formation, Cull and coworkers suggest that up to 150 mL of Ringer's lactate may be safely added as a diluent to each unit of packed RBC. [27] Therefore, blood inadvertently mixed with small amounts of Ringer's solution need not be routinely discarded. Dilution will allow for more rapid infusion by decreasing the blood viscosity, which is dependent on hematocrit, at the risk of increased volume. Alternatively, the direct addition of approximately 200 mL of normal saline to the bag of packed RBCs has been recommended to bring the hematocrit in the blood bag to approximately 45%.

## Rewarming

Blood is stored at approximately 4 °C to maintain cellular integrity and to prevent the overgrowth of microorganisms. Blood products usually passively warm to 10 °C by the time they are administered to the recipient. Adverse effects of hypothermia on cardiac conduction and flow rates are evident when rapid administration of a large volume of blood is performed without prewarming.

Various mechanisms have been used to warm blood to the ideal 35 to 37 °C. An ideal blood warmer should allow

liberal flow rates while preventing thermal hemolysis of blood cells. Commonly used devices are bath coils that allow a plastic tube to reside in a closely regulated warm water bath, as well as dry heat devices that allow blood to circulate through flat, thin bags sandwiched between aluminum

**Figure 29-10** (Figure Not Available) A controlled-pressure administration device for rapid infusion of blood products. *(Courtesy of Fenwal Laboratories, Deerfield, Ill.)*

blocks that contain electric heating elements. Both of these devices have relatively low flow rates and suboptimal thermal clearance. [28] Blood bag immersion in warm water baths is safe, but it is considered to be an imprecise and a slow method of rewarming. Although much interest surrounds

**Figure 29-11** (Figure Not Available) A rubber bladder is pumped up, and the blood unit is squeezed uniformly against a reinforced mesh. *(Courtesy of Fenwal Laboratories, Deerfield, Ill.)*

the use of microwave heating devices, the technique is not recommended by the Association of Blood Banks.

Rapid admixture warming is a promising alternative technique (see Chapter 23) . [29] The unit of whole blood is mixed with an equal amount of normal saline, which has been preheated to between 60 to 70 °C. Once mixed, the product is administered to the patient with a resultant delivery temperature of approximately 35 °C. This technique combines dilution of blood product and warming into one step. Regardless of the rewarming technique used, warming refrigerated blood to body temperature decreases its viscosity twofold to threefold and avoids venous spasm, thus facilitating transfusion.

## Monitoring

During the first 5 to 10 minutes and then every 15 minutes during a transfusion of any blood product, the patient must be carefully monitored for evidence of a transfusion reaction. Signs and symptoms that may be encountered are hives, chills, diarrhea, fever, pruritus, flushing, abdominal or back pain, tightness in the chest or the throat, and respiratory distress. A potentially life-threatening acute hemolytic transfusion reaction in a patient who has received prior transfusions may differ clinically from an allergic, nuisance reaction only by its effects on the patient's pulse and blood pressure. One can safely treat an allergic reaction to leukocytes or plasma proteins that cause hives, itching, fever, or chills by administering an antihistamine (but not into the blood infusion line) and stopping the transfusion.

When one encounters the following signs in a patient: an increase in pulse rate, a decrease in blood pressure, respiratory symptoms, chest or abdominal discomfort, or a sensation of "impending doom," one must *stop* the transfusion *immediately* and must infuse normal saline to maintain blood pressure and urine output. Samples of urine and blood should be sent to the laboratory to verify the presence of free hemoglobin. The blood bank should also receive a clotted sample of blood to reassess the presence of any immune reaction. If the conclusion of the blood bank evaluation is that the reaction is a nonhemolytic allergic response, premedication with antihistamines (diphenhydramine or hydroxyzine) and antipyretics is indicated before the next transfusion. Alternatively, washed cells could be used.

The patient in whom a hemolytic transfusion reaction is suspected should be treated vigorously and promptly. [30] Most mortality and morbidity is secondary to hypotension and shock leading to cardiovascular instability, renal insufficiency, respiratory manifestations, or hemorrhagic complications of disseminated intravascular coagulation. The initial treatment is directed at treating the hypotension by infusion of 5% dextrose in saline or lactated Ringer's solution or vasopressors, if required. The volume and rate of infusion are determined by blood pressure response. Symptomatic treatment with acetaminophen, a warming blanket, an inhaled or subcutaneous beta-agonist agent for bronchospasm or subglottic edema, or antipruritics or antihistamines is of secondary importance.

If an acute hemolytic transfusion reaction occurs, there may be some benefit from alkalinization of the urine with IV sodium bicarbonate to prevent the precipitation of free hemoglobin. Forced diuresis with mannitol to maintain the urine output at 50 to 100 mL/hour has also been advocated. The benefit from alkalinization and diuresis in the prevention of acute renal shutdown is uncertain, although the use of these techniques is commonly advocated. After shock is controlled, an assessment of hemostasis, respiratory function, renal function, and cardiac function will help direct later therapy of the complications; disseminated intravascular coagulation may call for the administration of plasma, platelets, or fibrinogen, and acute tubular necrosis may dictate careful fluid management. Hemolytic transfusion reactions have become unusual. They are rarely fatal and are usually attributable to an error in identification (such as can result from the treatment of two "John Doe" patients simultaneously).

Delayed, or "late," hemolytic transfusion reactions may occur days, or even weeks, after transfusion of RBCs. They are characterized by dropping hemoglobin levels, jaundice, hemoglobinemia, and indirect hyperbilirubinemia. [31] This complication is usually self-limited and is not life-threatening. Therapy is symptomatic, but future attempts at crossmatching for transfusions may be difficult because of the presence of RBC antibodies. Individuals so affected should wear identification tags or bracelets to alert medical personnel that prior transfusion reactions have occurred.

## CONCLUSION

On completion of a transfusion, an entry in the patient's record should be made to indicate the volume and nature of what was transfused and the presence or absence of

any reaction. The progress note, the transfusion record sheet, or the transfusion laboratory slip can be used for this purpose and should be signed and dated by the physician or nurse, in accordance with hospital policies. The bag in which the blood was stored might be discarded or returned to the blood bank, as individual policies dictate.

The practitioner should emphasize to the patient and family how critically important any blood transfusion is to the patient's care. It could then be suggested that the family consider arranging for replacement donations of units of blood to afford future patients the luxury of an ample, available supply of blood products.

# Chapter 30 - Pneumatic Antishock Garment

**Robert Norton**

Although a subject of much controversy, the pneumatic antishock garment (PASG) is widely available and commonly used, both by emergency medical technicians and paramedics in the out-of-hospital care of hypotensive patients and, to a lesser extent, by hospital emergency departments and critical care personnel. In its commercially available forms--MAST (David Clark Co., Inc., Worcester, Massachusetts) and Gladiator antishock pants (Jobst Institute, Inc., Toledo, Ohio) [1] --the PASG resembles a pair of high-waisted men's trousers. The devices are constructed from two layers of an opaque, airtight fabric sewn into three independently inflatable chambers (Figs. 30-1 (Figure Not Available) and 30-2) (Figure Not Available) .

These devices have been called by many names: MAST, military antishock trousers, medical antishock trousers, PASG, circumferential pneumatic compression device, shock pants, external counter pressure suit, air pants, MAST pants, MAST trousers, pressure pants, and G-suit. Other terms have been used to refer to the process of applying external pressure to the body, regardless of the device used. Examples are external (or circumferential) pneumatic compression and external counterpressure. [2] Because some of these names (e.g., MAST) are also registered commercial trademarks and because *pneumatic antishock garment* is the term adopted by the American College of Surgeons for its Advanced Trauma Life Support course, [3] PASG is used in this chapter to refer to the devices that are currently available.

Regardless of the name, the device has changed little in its design or application since 1903, when Crile created a "pneumatic suit" from a double layer of rubber. [4] One or both legs or the abdominal compartment could be inflated separately with a bicycle pump. Designed to manipulate blood pressure during head and neck surgery in the sitting position, the pneumatic suit was subsequently applied to the management of the trauma patient. [5] Leaks in the material inhibited widespread use of the device, and the principle of external counterpressure lay dormant until its rediscovery by the military (allegedly at Crile's suggestion) during World War II. [6] Reincarnated as the G-suit, the garment was used to provide momentary compression of up to 100 mm Hg to counteract the cerebral and retinal ischemia (with resultant loss of consciousness or vision) that occurred during certain maneuvers in high-speed aircraft. Medical interest was renewed with investigations performed by Gardner and Dohn. [7] They used a homemade G-suit in patients who were likely to experience postural hypotension (e.g., neurosurgical patients in the sitting position, patients in whom spinal anesthesia had been administered, and those with severe diabetic neuropathy). Their device subsequently became commercially available and consisted of a double-layered rectangular blanket wrapped completely around the patient from xiphoid to ankles. For the next decade or more, external counterpressure was used only in the hospital setting and usually as a last resort in cases of uncontrollable postoperative hemorrhage (Table 30-1) .

| TABLE 30-1 -- Early Uses of the PASG Device |

| Lower extremity fractures |
| Placenta percreta |
| Gastrointestinal bleeding |
| Ruptured ectopic pregnancy |

The military G-suit experience during the Vietnam War was the first recorded routine use of the external counterpressure principle in the preoperative stabilization of trauma patients. [8] The Army continued to develop the device until the current pants-like form was achieved. [9] The inventor of the modern-era trousers, B. H. Kaplan, became the first to adapt them to their next area of extensive use: civilian out-of-hospital application by paramedics and emergency medical technicians.

## MECHANISM OF ACTION

The mechanism of action of PASG has been the object of many experimental studies. Interpretation and comparison of results from these studies require attention to several factors: species of subjects, volume status, design of garment, inflation pressures, methods of hemodynamic measurements, and position of subjects (supine or tilted). The increase in blood pressure that results from application of PASG is due to at least three effects: enhanced venous return (autotransfusion), increased total peripheral resistance, and reduced volume loss from control of hemorrhage (Table 30-2) .

**Enhanced Venous Return**

The improvement in blood pressure seen during early PASG device studies was assumed to result from "autotransfusion" of blood from the venous system of the lower extremities and the splanchnic bed to circulation above the diaphragm. Reports stated that this mechanism could account for volumes of transfusion as large as 2 units (1000 mL) of blood, [11] yet experimental evidence to support such a large volume change has

not been found.

Increased central blood volume in humans after PASG application has been demonstrated by changes in thoracic radioactivity after 131 I-labeled albumin injection [12] and using a measurement of 99m Tc-labeled albumin. [13] Changes in normovolemic subjects are most marked when venous pooling is increased by tilting. [14] Attempts at quantification of "autotransfusion" in humans using nuclear scanning after radioactive red blood cell injection [15] have estimated that only 150 to 300 mL is actually autotransfused.

**Increased Total Peripheral Resistance**

Another explanation for the increase in blood pressure is an increase in total peripheral resistance after PASG application. This phenomenon has been well characterized in normovolemic and hypovolemic animal models. [16] [17] Using a hemorrhagic canine model, Niemann and colleagues demonstrated

| **TABLE 30-2** -- PSAG: Proposed Mechanisms of Action |

| Effects on bleeding vessels |

|  |
|---|
| Decreased transmural pressure |

progressive increase in total peripheral resistance with inflation pressures of 40, 60, and 100 mm Hg. [16] Greater increases in total peripheral resistance occurred in the normovolemic group. Cardiac output increased only in the hemorrhagic hypovolemic group.

Hemodynamic responses to PASG in volunteer subjects are variable and sometimes contradictory. In normovolemic subjects, increases in central venous pressure and intrathoracic blood volume have been demonstrated following inflation of the PASG. [12] However, Burchard and colleagues reported no change in the cardiac index in 10 subjects after coronary artery bypass surgery, despite an increase in central venous pressure and left atrial pressure. [18] Using thermal dilution catheters in 10 subjects undergoing diagnostic cardiac catheterization, Rubal and associates found no increase in cardiac output or stroke volume, despite an increased total peripheral resistance and central venous pressure. [19] Using Doppler measurements, Hauswald and Greene reported no change in cardiac output in 10 healthy volunteers, despite a 75% reduction in aortic flow distal to the superior mesenteric artery and a 10% increase in blood pressure. [20] In a similar study using a head-up tilt to model hypovolemia in healthy volunteers, Mannering and associates found that PASG increased cardiac output and forearm blood flow in tilted patients. [21] Gaffney and colleagues found an elevated blood pressure and peripheral resistance with a decreased cardiac output and stroke volume during supine PASG application, but when the subjects were tilted 60° (head up), PASG produced a small elevation in stroke volume. [14] Savino and colleagues studied PASG use in elderly normovolemic patients and demonstrated a progressive decrease in the cardiac index and impairment in left ventricular function with increasing inflation pressures for half their patients. [22] Payen and coworkers demonstrated a significantly increased cardiac index in ventilated patients on positive end-expiratory pressure (PEEP) after inflation of PASG using pulmonary artery thermal dilution catheters to measure cardiac output. [13]

The conflicting results seen in animal and human studies can be explained in part by the volume status of subjects before inflation of the PASG, the overall effect of the subjects' homeostatic responses to increased afterload and preload, and the timing of the hemodynamic measurements. [23] Young normovolemic volunteers rapidly react to increased afterload, as manifested by an increased total peripheral resistance, with a change in heart rate or stroke volume--hence, their cardiac output may not change. Also, with normovolemia, changes in preload will have little effect on cardiac output. [17] Although no controlled hemodynamic studies have been done on hypotensive, hypovolemic volunteers, the effect is expected to be similar to the response in tilted subjects or hypovolemic animals. In that setting, the predominant response is an increase not in afterload but in preload, which results in increased stroke volume and, consequently, improved cardiac output for a variable duration. [17] [21] The complete

explanation for the mechanisms of action of PASG awaits further clinical research.

**Control of Hemorrhage**

The PASG can serve as a pressure dressing over external bleeding sites. Acting as a pneumatic splint, the device prevents continued bleeding provoked by motion at fracture sites. This is particularly efficacious with long-bone fractures and with retroperitoneal bleeding from pelvic fractures. In the management of hemorrhage associated with major pelvic fractures, the use of the PASG has been recommended as part of the initial management, followed by external fixation, surgery, or selective angiographic embolization. [24] One review of pelvic fractures has demonstrated radiographic realignment of an open-book, diastasis-type pelvic fracture after inflation of the PASG. [25] The PASG, combined with other nonsurgical therapy, also has been reported to be effective in controlling nontraumatic pelvic hemorrhage in obstetric and gynecologic patients. [26]

Principles of physics have been used to explain how external counterpressure can reduce flow from a sizable vascular defect while still allowing blood to circulate. [20]

*Laplace's law* ($T = \text{DeltaP} \times R$) determines the wall tension (T) for a cylinder (Fig. 30-3) (Figure Not Available) . T is the force tangential to the circumference of the vessel that tends to pull apart the edges of a longitudinal laceration (L in Fig. 30-3) (Figure Not Available) . Transmural pressure (DeltaP) is the difference between the intraluminal ($P_I$ ) and extraluminal ($P_E$ ) pressures ($\text{DeltaP} = P_I - P_E$ ). Increases in $P_E$ are produced by the PASG, and the tendency to bleed (DeltaP, T) declines. In addition, circumferential pressure causes the radius of the vessel (R) to decrease, limiting both of these contributions to the wall tension.

*The Bernoulli principle* takes more factors into account (Fig. 30-4) . It relates the rate of flow from the injured vessel (Q) to the surface area of the laceration site (A), transmural pressure (DeltaP), density of the fluid medium (rho), and the velocity (V) of the fluid flowing through the vessel. In this model the major action of the external counterpressure suit

is to limit transmural pressure along with the surface area of the laceration (Fig. 30-5) (Figure Not Available) . Many animal studies have tested these relationships, and nearly all models document decreased flow through lacerated vessels with external counterpressure and support one or the other of the equations listed.

# INDICATIONS

The list of clinical applications for PASG is modified frequently as new suggestions appear in the literature (Table 30-3) . Many indications that were controversial in the past are no longer so as experience with the PASG has increased. There are limited experimental and clinical data to support some suggested indications. Obviously, specific therapy directed at the underlying cause of the patient's illness or injury is the mainstay of successful treatment of any condition that may respond initially to the

supportive use of counterpressure.

**Hypovolemic Shock**

Several reports from Mattox and colleagues have changed the indication regarding the use of PASG for hypovolemic shock resulting from penetrating trauma. In a randomized clinical trial evaluating out-of-hospital trauma scores, fluid administration, emergency department and operative

management, and survival, the investigators reported no advantage for use of the PASG in shock caused by penetrating abdominal injuries. [31] A continuation of the same study concluded that the PASG may be harmful when used with hypotensive patients who have penetrating thoracic wounds. [32] The study was conducted in an urban emergency medical services system with mean transport times <15 minutes and permitted concurrent out-of-hospital administration of large volumes of crystalloid fluid. Although no comparable controlled trials have been done for rural systems or for blunt abdominal trauma only, Chang and colleagues [33] used a prospective study design similar to that used by Mattox and colleagues [30] [31] [32] in a "medium-sized" urban community in which 50% of eligible patients had sustained blunt trauma. Although their series was small and a large proportion of cases assigned to the PASG group were excluded because of nonuse of the device, no differences in clinical outcomes were noted.

A retrospective study of patients who were severely hypotensive (systolic blood pressure, 50 mm Hg) as a result of both blunt and penetrating trauma found an improvement in survival associated with PASG use. [34] The authors concluded that the use of PASG in trauma patients with this degree of hypotension should be considered acceptable.

Recent animal models support the use of PASG in hemorrhagic shock and abdominal trauma. Using a controlled hemorrhagic shock model in sheep, Landau and coworkers found significant increases in mean arterial pressure, cardiac output, and tissue perfusion when PASG application was combined with hypertonic saline infusion. [35] Ali

and Duke studied a canine blunt splenic injury model and demonstrated improved survival and maintenance of carotid artery pressure along with decreased splenic and aortic blood flow after PASG inflation. [36] In an otherwise lethal abdominal aortic laceration model in pigs, Ali and associates found improved survival and decreased hemorrhage after PASG inflation. [37] However, in a prolonged (4-hour) hypotensive hemorrhage porcine model without concurrent volume resuscitation, PASG use was associated with greater fluid deficit, lactic acidosis, tissue edema, and hyperkalemia. [38]

In a retrospective study comparing air and ground transport of patients with primarily blunt multi-organ trauma, Moylan and associates identified use of PASG as one of several interventions in the air-transported group that were associated with improved survival. [39]

There are a number of advantages of the PASG over massive fluid replacement alone for patients with hypovolemic shock. The device is quickly applied and offers some immediate pressor response. Collapsed peripheral veins may become easier to cannulate after inflation. PASGs can be applied by persons without IV therapy skills, and the compressive effect may reduce hemorrhage from pelvic and intra-abdominal vessels.

Hence, until further studies clarify the exact role of PASGs in the management of trauma patients with hypovolemic shock, it seems prudent to continue to use them for selected patients with blunt trauma and severe hypotension (systolic blood pressure, <80 mm Hg); for patients with penetrating abdominal trauma and hypotension, *combined with* long transport times when out-of-hospital IV fluid therapy is not available; and for patients with signs of shock from other causes of hypovolemia.

## Other Uses During Hemorrhage

"Prophylactic" application (with or without inflation) may be helpful in potentially hypovolemic or hypotensive patients. Examples are patients with gastrointestinal bleeding or those with leaking abdominal aortic aneurysms. In patients with leaking abdominal aortic aneurysms, one should maintain the systolic blood pressure at approximately 100 mm Hg to avoid contributing to further hemorrhage. [42] [43] Pelvic or lower extremity fractures are well stabilized by these devices, adding significantly to the patient's comfort. [24] [25] The PASG may serve as a compression dressing over external bleeding. Controlling postoperative intra-abdominal hemorrhage has been a classic indication. [2] Bleeding aggravated by coagulation defects has also been responsive to external counterpressure. [44]

## States of Relative Hypovolemia and Hypotension

Other causes of shock in which the pneumatic suit might be helpful but for which data are limited include neurogenic (spinal) shock, shock secondary to anaphylactic shock, [45] drug overdose [46] and septic shock.

### Cardiopulmonary Resuscitation

Interest in the use of external counterpressure devices during cardiopulmonary resuscitation (CPR) is a result of recent changes in the way that blood flow is believed to occur during external chest compression (see Chapter 16) . During adult CPR, the "thoracic pump" mechanism of blood flow often predominates, and chest compression serves to raise intrathoracic pressure. Blood flows because of pressure gradients developed between intrathoracic and extrathoracic vessels. External counterpressure from the PASG is believed to augment CPR in two ways: (1) by reducing diaphragmatic excursion and therefore increasing intrathoracic pressures during compression, and (2) by compressing the infradiaphragmatic vascular bed, producing selective perfusion of vital structures above and increased peripheral resistance below the diaphragm.

Lilja and coworkers noted that PASG increased systolic blood pressure during CPR in 7 of 8 patients. [47] However, Mahoney and Murick reported no difference in initial resuscitation or survival between standard CPR and PASG-augmented CPR in a clinical, out-of-hospital study. [48] A review by Niemann and colleagues concluded that the use of PASG as an adjunct to CPR has not been proven to be beneficial and should remain experimental. [49]

### Paroxysmal Supraventricular Tachycardia

Case reports have documented cardioversion of paroxysmal supraventricular tachycardia to a sinus rhythm after the application of PASG in adults [50] and in a child. [51] The mechanism for the response has been attributed to reflex vagal excitation from increased aortic and carotid sinus pressure.

## CONTRAINDICATIONS

Pulmonary edema, congestive heart failure, and penetrating thoracic trauma are the current absolute contraindications to the use of PASGs (Table 30-4) . The increased venous return, decreased vital capacity, and elevation in pulmonary wedge pressure produced by these devices may aggravate preexisting pulmonary congestion.

### Penetrating Thoracic Injuries

External pressure applied below the diaphragm can increase the rate of blood loss from thoracic injuries. In a porcine model of thoracic aorta laceration, PASG inflation increased hemorrhage and mortality. [53] A retrospective review of penetrating cardiac wounds demonstrated an association between PASG inflation and a seven-fold lower survival rate. [54] In addition, Mattox and colleagues, in a large clinical trial, found that PASG use coupled with aggressive fluid resuscitation in hypotensive patients with penetrating thoracic injury was deleterious. [32] Finally, diaphragmatic injury may result in herniation of abdominal contents into the thorax. [55] Hence, use of PASG in the setting of penetrating thoracic injury is contraindicated.

## Cardiogenic Shock

Wayne has advocated the use of the PASG as a quickly reversible "fluid challenge" in patients with cardiogenic shock. [56] The intended use is to identify those patients in cardiogenic shock who might benefit from volume resuscitation and thus guide crystalloid infusion therapy in those individuals. Pressor agents are reserved for those patients who fail to improve or worsen with inflation. The complete

| TABLE 30-4 -- Proposed Contraindications to PASG Application |

| Penetrating thoracic injuries |
| Relative contraindications |
| Pregnancy |
| Evisceration |
| Impaled foreign body |
| Lower extremity compartmental injury |

| |
|---|
| Lumbar spine instability |

"reversibility" of the effects of the device has not been well documented, particularly in the setting of a poorly functioning cardiovascular system. Five minutes into PASG inflation, central venous pressure, cardiac index, pulse, and central blood volume return to preinflation values. With the release of PASG pressure, the cardiac index increases to compensate for a fall in blood pressure and central venous pressure. [57] The changes after deflation are attributed to unmasking of the compensatory mechanisms (probably vasodilation) that had taken place during external counterpressure to normalize the patient's hemodynamics. Thus, mere removal of these devices after application does not necessarily restore the patient's cardiovascular system to a "baseline" state. In light of the short-lived effect seen with PASG inflation and the potentially deleterious effects following PASG deflation, use in the setting of cardiogenic shock is contraindicated.

## Relative Contraindications and Controversial Applications

Other relative contraindications that have been proposed include pregnancy, evisceration of abdominal contents, a foreign body impaled in the abdomen, and lumbar spine injury. For these situations, the leg chambers may be inflated without additional risk, and the relative risks and benefits of inflation of the abdominal binder can then be assessed. Circumferential burns and other injuries that suggest lower extremity compartmental injury also represent significant relative contraindications. Application of external counterpressure elevates the limb compartment pressure and increases muscle ischemia.

The use of the PASG in the patient with a penetrating abdominal injury in the setting of a rapid transport time and concurrent IV therapy does not appear to be advantageous. [30] [31] [32] Finally, because the hemodynamic response to PASG inflation is quite variable and at times deleterious in the elderly, [22] advanced age represents a relative contraindication to PASG use.

There are a number of situations in which PASG use has been discouraged by early writers. Although few data address these circumstances, some general review articles have discussed the judicious use of external counterpressure in these controversial settings. [58] [59] [60]

### Head Injuries

The only purely intracranial injury that can produce shock is transtentorial herniation. In the absence of this often fatal injury with its unique signs and symptoms, shock is usually the result of associated visceral injuries or spinal cord injury. However, fear that the PASG would increase cerebral edema and intracranial pressure has caused manufacturers to interdict use of the device in head injury. Several animal experiments

have found no significant effects of PASG inflation in hypovolemic or normovolemic dogs with or without an experimental "intracranial mass." The studies did document improvement in cerebral perfusion pressure with PASG use. [61] [62] [63] Gardner and colleagues evaluated the use of the PASG in 12 patients with severe head injury and an intracranial pressure <20 mm Hg. [64] They found increases in mean arterial pressure and cerebral perfusion pressure without adverse effect on intracranial pressure as long as the inflation pressure was <60 mm Hg. The use of PASG in patients with significant underlying elevations in intracranial pressure has not been studied.

**Cardiac Tamponade and Tension Pneumothorax**

Fluid infusion is a standard temporizing measure in cardiac tamponade. In a dog model of experimental cardiac tamponade, PASG inflation produced a doubling of mean arterial pressure and temporarily improved cardiac output. [65] Hence, the use of the PASG has been suggested in this setting when persons skilled in IV therapy and subsequent definitive treatment are unavailable. Tension pneumothorax is a similar state of compromised venous return that also might respond temporarily to the redistributed fluid volume resulting from PASG application. Palafox and associates, however, produced cardiac tamponade or tension pneumothorax in hypovolemic dogs and found a *decline* in arterial pressure and a rise in central venous pressure when the abdominal binder was inflated above 80 mm Hg. [63] This deterioration was believed to be caused by PASG-induced diaphragmatic elevation, which increased intrathoracic pressures and further compromised venous return. The clinical investigation of Mattox and coworkers suggests that IV therapy without PASG is safer in the patient with a penetrating thoracic injury during rapid transport for definitive therapy. [32] Hence, PASG use in hypovolemic patients with suspected cardiac tamponade or tension pneumothorax is relatively contraindicated.

# EQUIPMENT

Two of the principal manufacturers of PASGs are Jobst Institute, Inc., in Toledo, Ohio, which produces the Gladiator Antishock Pants, and David Clark Co. in Worcester, Massachusetts, which produces the MAST. Both brands come in two different sizes: adult and pediatric. Some features include X-ray transparency, perineal opening, and the ability to be applied over and under most traction splints. The trousers come with or without a gauge for monitoring air pressure. Advantages of using models with pressure gauges include the ability to (1) assess PASG inflation pressure during deflation for removal; (2) monitor garment pressure during air transport of the patient (in unpressurized aircraft); (3) evaluate PASG pressure in settings of environmental extreme temperatures; and (4) detect damaged air chambers, tubing, etc. The cost for a PASG, pump, and other equipment ranges from $535 to $640 for the adult size without gauges and $597 to $853 for the adult size with gauges. The cost for the pediatric size ranges from $465 to $806 for a unit without gauges and from $540 to $980 for a unit with gauges.

# PROCEDURE

**Application of PASG**

Before PASG application, it is useful to inspect the device and to establish the proper orientation (Fig. 30-6) (Figure Not Available) . Many find it helpful to mark the "up" side (inside) with paint or tape to aid in rapid correct application. The patient can be "logrolled" onto the opened trousers. Alternatively, with one person standing on either side and elevating the patient's

**Figure 30-6** (Figure Not Available) Pneumatic antishock garment application. (Courtesy of the American College of Surgeons, Committee on Trauma.)

legs, the trousers can be slid beneath to the buttocks. Then the patient's hips are elevated slightly, and the upper border of the trousers is placed at the costal margin. The cervical spine must be stabilized in those at risk for cervical injury. The medial portion on each leg binder is brought between the legs, and the Velcro fasteners are closed over each leg and over the abdomen.

Some emergency departments prefer to keep the deflated PASG on the resuscitation table at all times. When patients arrive, they are placed on the garment so that it is immediately accessible should its use be required later during treatment. An alternative is to assemble the trousers loosely in advance and slide them over the patient's legs. [66] During application, the operator places his or her own arms through the pants legs from the bottom, sliding the pants legs completely onto the arms. The operator then stands at the patient's feet, grabs the patient's toes, and lifts. An assistant pulls the trousers from the operator's arms and slides them over the patient, and the Velcro straps are retightened.

After device application, the foot pump hoses are attached to the stopcocks, and the foot pump is used to inflate the two leg compartments and then the abdomen. The operator can accomplish inflation faster if the compartments are initially filled by blowing into them. The lungs can provide volume more quickly than the pump during initial low-resistance inflation. After resistance to filling is met, the pump becomes more efficient at increasing trouser pressures. [66] Hanke and associates found no difference in redistribution of blood volume between simultaneous and sequential inflation of the leg and abdominal compartments. [67] Jennings and coworkers similarly found no hemodynamic benefit to simultaneous device inflation. [68] Therefore, it seems prudent when using the device for hypotension to inflate the leg compartments first and then check the blood

pressure. If an adequate blood pressure is obtained, the abdominal compartment does not need inflation. If the blood pressure is inadequate, the abdominal compartment is inflated. Blood pressure and pulse should be closely monitored during the procedure, and inflation should be stopped if the systolic blood pressure exceeds 100 mm Hg.

Pediatric devices are available, although they are used infrequently. In the absence of these smaller garments, one can efficiently manage small children by wrapping them in one leg of the adult-sized trousers. A folded sheet or blanket can be placed between the

bony prominences of the lower extremities. The inflation pressure should be titrated to a satisfactory pulse and blood pressure response.

The PASG alone can passively splint lower extremity fractures. Of the commonly available traction devices, only the Sager traction splint can be applied after the trousers are in place and inflated. The Sager splint can be used either inside or outside the device to splint one or both legs at the same time. The Hare traction splint and the Thomas splint are significantly more awkward to use with the PASG inflated. The Hare and Thomas splints present some risk of damage to the trousers themselves and result in uneven application of circumferential pressure (see Chapter 49) . As discussed later, the application of traction in combination with external counterpressure exacerbates compartmental pressures in the lower extremities. [69]

## Inflation Pressure

Of the two major PASG devices that are available, only one, the Jobst Gladiator, has a pressure gauge (or gauges) for monitoring pants pressure. As with any such piece of equipment, gauges should be periodically checked for accuracy. The other device uses pressure-relief ("pop-off") valves that limit inflation pressures to 104 mm Hg. It is reasonable to assume that most side effects and complications of these devices are proportional to the magnitude of PASG pressure and duration of pressure application. Most animal experiments and some clinical studies have suggested that hemorrhage control (presumably control of venous bleeding) in otherwise stable (often postoperative) patients is often accomplished with <40 mm Hg of inflation pressure. [2] "Autotransfusion" and blood pressure elevations may require a higher inflation pressure, although Hanke and colleagues reported a significant increase in central blood volume at 40 mm Hg and only minor progressive increases at 100 mm Hg. [67] Wayne and MacDonald suggested that most out-of-hospital patients in shock will not demonstrate blood pressure elevation at a 30-mm Hg inflation pressure. [70] The goal is to achieve a systolic blood pressure of approximately 100 mm Hg at the lowest inflation pressure possible. Obviously, time constraints may not permit careful titration of inflation pressure to blood pressure response; the patient in extremis may need simultaneous inflation of both leg and abdominal compartments to 100 mm Hg immediately on presentation.

## Deflation

### When?

In the usual case, deflation may be considered when the combination of PASG and other resuscitative measures (e.g., fluids, hemorrhage control) has resulted in restoration of satisfactory vital signs. The gradual deflation procedure to be outlined should be followed. The presence of any contraindications to continued use (e.g., congestive heart failure, renal disease, pulmonary disease) should also be considered. The presence of a coagulopathy may be a relative contraindication to removing the device.

**Where?**

If emergency surgery is indicated, the operating table may be the best place to deflate the PASG. After all monitoring and venous lines have been started, the anesthesiologist is prepared to monitor the patient, and the surgeons are in attendance, the abdominal portion can be deflated (preferably slowly--see next section). The leg compartments can be left inflated for an abdominal procedure until internal hemorrhage is better controlled. In most situations, after adequate volume resuscitation, PASG deflation can be safely performed in the emergency department.

**How?**

The PASG should be deflated gradually. Rapid deflation of the PASG in the hypovolemic patient can result in a catastrophic drop in blood pressure. The hemodynamic changes seen during deflation result from a rapid reduction in left ventricular afterload followed by a decrease in preload. [71] This process may be exacerbated by the sudden release of lactic acid and other vasoactive chemicals pooled in the abdomen and the lower extremities. [8] [72] Hence, deflation, particularly in the setting of prolonged PASG use, should be approached with caution.

Deflation should begin with the abdominal compartment. Small quantities of air are released, and the patient's blood pressure is rechecked. If no blood pressure drop occurs, more air should be released with repeated blood pressure measurements. If the systolic blood pressure falls >5 mm Hg, deflation should be halted and more fluids given until blood pressure is restored. After the abdominal compartment is deflated, the legs should be deflated in a similar manner.

## COMPLICATIONS AND DISADVANTAGES

A number of specific adverse effects have been noted in association with PASG use (Table 30-5) . In addition, patients with penetrating abdominal and thoracic trauma whose management included PASG use in conjunction with vigorous out-of-hospital fluid resuscitation have been reported to have an increased mortality rate when compared with patients treated with fluid resuscitation alone in one urban out-of-hospital setting. [31] [32] As noted in the Indications and Contraindications sections, the use of PASG in patients with penetrating truncal injuries in the setting of rapid transport times or IV fluid therapy does not appear to be warranted. Further discussion of other specific complications follows.

**Hypotension**

Clinical experience has shown that the major life-threatening complication resulting from the use of the PASG in hypovolemic patients is sudden and severe hypotension resulting from precipitous removal of the device in the absence of adequate fluid resuscitation. [8] [41] Although emergency department

physicians and emergency medical technicians are well aware of the problem, many consultants are not. When faced with a patient encased in vinyl from xiphoid to ankles, some consultants have rapidly removed these devices, often with disastrous consequences.

**Metabolic Acidosis**

Metabolic acidosis has been the most reproducible abnormality after application of external counterpressure. Wangensteen and associates first reported this "detrimental" effect of external counterpressure. [73] They noted acidosis (to a pH of 7.01) and an increased lactate-to-pyruvate ratio in hypovolemic dogs after 4 hours of external counterpressure. Hypovolemic dogs without external pressure had less acidosis and

lived longer. Although treatment of hypovolemia with a PASG alone and without concomitant fluid replacement is an unusual situation, these animal studies led to the recommendation to limit PASG application time. Human studies have shown mild metabolic acidosis (pH 7.33 to 7.36), and other reports suggest that the acidosis is not a problem clinically. [74] [75] Although metabolic acidosis may occur, close monitoring of arterial blood gases and correction with bicarbonate as needed should adequately address this potential problem.

## Respiratory Compromise

Abdominal binding invariably produces subjective effects on respiration; alert patients frequently complain of shortness of breath when the abdominal compartment is inflated. However, McCabe and colleagues found no changes in inspiratory and expiratory reserve volumes, maximum breathing capacity, or tidal volume in their volunteers. [76] Similarly, Batalden and coworkers found no pulmonary complications in 10 patients with external counterpressure garments who underwent positive-pressure ventilation for 24 to 48 hours. [77] However, Burdick and colleagues found atelectasis, pulmonary edema, or pneumonia in 14 of 28 similar patients. [75] Cogbill and coworkers demonstrated mild impairment of pulmonary function in healthy individuals and those with airflow obstruction when the PASG was inflated. [78] The impairment was restrictive rather than obstructive and was not clinically significant with inflation pressures <50 mm Hg. Some studies suggest that impaired pulmonary function results from mechanical binding of the thorax and decreased excursion of the diaphragm. [76] [79] Newer designs of the device incorporate smaller abdominal compartments, which should not be applied at or above the costal margin and have resulted in less restriction of vital capacity. [76] In general, investigators concerned about respiratory compromise have recommended careful attention to arterial blood gases combined with controlled positive-pressure ventilation in those patients requiring prolonged external counterpressure. [11] [75]

## Decreased Renal Perfusion

In one study, 10 subjects in PASGs for 4 to 24 hours had no significant alterations in renal blood flow. [80] However, reversible abnormalities in renal hemodynamics have been reported with external counterpressure. Normal human subjects experiencing increased abdominal pressure had a 24 to 48% decline in effective renal plasma flow and glomerular filtration rate, decreased urine output, elevated renal vein pressures, and increased urine specific gravity. [81] These changes reversed after decompression.

## Infrequent Complications

A number of case reports document some infrequent but serious complications of the PASG.

*Pulmonary edema and congestive heart failure* have been attributed in isolated cases to increased pulmonary venous return and elevated pulmonary capillary wedge pressures. [2] [75]

*Lumbar spine instability* is another potential complication of the PASG. Older PASG designs included an abdominal bladder that inflated in the back as well as over the abdomen. Rockwell and coworkers reported a case in which a lumbar spine injury was believed to have been aggravated by inflation of a circumferential abdominal bladder. [82] They also demonstrated graphically on a volunteer the marked exaggeration of lumber lordosis that is possible with the older style garment. Newer designs of commercially available suits limit inflation to the anterior aspect of the abdominal compartment. The abdominal portion of all designs of the PASG should be used cautiously in patients at high risk for an unstable lumbar spine injury.

*Lower extremity compartment syndromes* following use of PASG have been reviewed elsewhere. [83] Increased pressure within the limits of a fascial compartment results in impaired microcirculation. The compartment pressure under the PASG is dependent on the PASG inflation pressure, the mean arterial pressure, and the application of passive traction. [69] [84] During hypotension, with full PASG inflation, the compartment pressure may exceed the mean arterial pressure. [84] Many factors contribute to the development of a compartment syndrome, including prolonged shock, inflation pressure (and duration of inflation), reperfusion edema, and local tissue injury. [83] It is not completely understood which of the multiple factors are most significant in the compartment syndrome associated with PASG use. Some cases are related to a lower extremity fracture with prolonged application of

PASG, [85] but other cases have occurred in the absence of lower extremity injury. [86] Improper deflation technique (i.e., leaving the abdominal compartment inflated after deflation of the extremity compartments) may facilitate the syndrome. [87] The overall frequency of this complication seems quite low. In their review of 1120 patients, Wayne and MacDonald reported no cases of compartment syndrome. [70] Mattox and associates found an incidence of anterior compartment syndrome in approximately 1% of their PASG patients and none of the patients without PASG. [30]

*Increased bleeding from lower extremity wounds* after suit inflation was attributed in 2 cases to improvements in blood pressure. [8] The bleeding responded to rebandaging but required temporary deflation of the suit. Such bleeding may be hidden in bandages under the devices and should be considered in the differentiation of persistent hypotension from other conditions.

*Stimulation of urination, defecation, and vomiting* by suit inflation was noted as a complication in early papers. [40] Spontaneous defecation has been a "complication" in patients being treated for gastrointestinal bleeding with these devices. [78]

*Skin breakdown at pressure points* with prolonged use has prompted the suggestion to pad bony prominences. [77]

*Diaphragmatic herniation* has been reported following PASG inflation. [55] A sudden deterioration in blood pressure or respiratory status following PASG inflation should alert the clinician to this possibility. Using a porcine model of diaphragmatic injury, Ali and Qi demonstrated a significant increase in mortality rate after PASG as a result of

cardiorespiratory deterioration caused by the increase in intra-abdominal pressure. [88] If significant herniation of abdominal contents into the thoracic space has occurred, deflation of the device may not fully resolve the clinical deterioration.

## Mechanical Problems and Disadvantages

### Limitation of Diagnostic Evaluation and Therapeutic Procedures

Physical examination of the lower extremities and the abdomen is limited by the PASG. A transparent suit that allows visualization of the lower extremities has been marketed but has other disadvantages and is not commonly used. For the more common nontransparent device, the examiner must not remove the suit precipitously. In a stable patient, one compartment at a time should be deflated slowly, with careful monitoring of vital signs. If necessary for treatment of hypotension, the compartment that has just been deflated may be reinflated. Similar problems exist with the performance of diagnostic peritoneal lavage. Urinary catheterization is challenging, particularly in female patients, even with the opening provided in the garments.

Vascular access also can be a problem. Lower extremity cutdowns are difficult to perform, and a pressure bag is required to produce flow of IV solutions. However, pressurized IV fluid infusion beneath inflated PASGs reaches the central circulation promptly and in significant amounts. [89] Access to the femoral artery and vein with the PASG inflated also is severely limited, although newer designs incorporate openings at the inguinal area for better access.

### Environmental Influences on Device Pressures

With the current popularity and availability of helicopter ambulance transport, the role of Boyle's law (i.e., the volume of gas is inversely proportional to its pressure) must be reemphasized. [90] [91] As the helicopter rises, the air in the suit expands, increasing the trouser pressure. Decreasing altitude has the opposite effect. Similarly, as ambient temperature increases, trouser pressure rises, and vice versa. Most helicopter transports occur at sufficiently low altitudes that the effects of altitude are not of concern, but when the "optimal" inflation pressure is determined at the scene of the injury, changes produced by movement into the controlled climate of the ambulance or hospital must be predicted and recognized.

# CONCLUSION

The PASG is a useful adjunctive device in the care of the hypotensive patient. When the garment is used, improvements in blood pressure and pulse are often dramatic. In certain situations the device may slow hemorrhage, and external counterpressure can "buy time" until definitive therapy is instituted. A major hazard is the profound hypotension that can result from precipitous removal of the device by those who are unfamiliar with this possibility. Although the device is not helpful in the urban out-of-hospital setting for management of penetrating trauma when crystalloid therapy is

rapidly available, it appears to have a role in other settings.

# Chapter 31 - Local and Topical Anesthesia

**Michael Orlinsky, Edwin Dean**

The use of local anesthetic agents is an important aspect of the everyday practice of emergency medicine. This chapter provides an understanding of the mechanism of action; the nuances of clinical use; and the prevention, recognition, and treatment of adverse reactions to commonly used anesthetics. Detailed technical guidance for the performance of topical and infiltrative local anesthesia is provided.

## BACKGROUND

The first local anesthetic was cocaine, an alkaloid contained in the leaves of the *Erythroxylon coca* shrub from the Andes Mountains. Early Incan society used cocaine for invasive procedures, including cranial trephination.

In 1884, Koller, a colleague of Freud, used cocaine topically in the eye and is credited with the introduction of local anesthesia into clinical practice. [1] In the same year, Zenfel used a topical solution of alcohol and cocaine to anesthetize the eardrum, and Hall introduced the drug into dentistry. [2] In 1885, Halsted demonstrated that cocaine could block nerve transmission and laid the foundation for nerve block anesthesia. [3] The search for alternatives to cocaine led to the synthesis of the benzoic acid ester derivatives and the amide anesthetics.

Although local anesthetics had been used for more than half a century, it was not until the 1960s that a specific understanding of the physiochemical properties, mechanism of action, pharmacokinetics, and toxicity of these agents emerged.

## PHARMACOLOGY AND PHYSIOLOGY

### Chemical Structure and Physiochemical Properties

Most useful local anesthetic agents share a basic chemical structure:

Within this basic structure, each agent's specific chemical composition determines its main physiochemical properties: negative log of dissociation constant (p$K_a$ ), partition coefficient (a measurement of lipid solubility), and protein binding. Each property, in turn, is the principal determinant of an agent's pharmacologic activity: onset of action, potency, and duration of action, respectively. However, in vivo the activity of a given agent may be altered by other factors unrelated to physiochemical properties, and therefore the relationship between physiochemical properties and clinical activity is not exact.

The linkage (intermediate chain) between the aromatic and hydrophilic segments is either an amino-ester or an amino-amide; these two chemical structures form the basis for the two main classifications of local anesthetics. *Ester*-type agents include procaine,

chloroprocaine, cocaine, and tetracaine. The *amide*-type agents include lidocaine, mepivacaine, prilocaine, bupivacaine (Marcaine), and etidocaine. The main difference between esters and amides is their metabolic pathways. Esters are hydrolyzed by plasma pseudocholinesterase, whereas amides are metabolized in the liver through enzymatic degradation. Within the ester or amide group, alterations in chemical structure to either the aromatic or the hydrophilic portion may affect the rate of metabolism and create a different activity profile for each agent within a given group.

Chemically, local anesthetics are poorly soluble weak bases. To be commercially available in solution, an agent is combined with hydrogen chloride to produce the salt of a weak acid. In the resulting acidic solution, salts exist both as uncharged molecules (nonionized) and as positively charged cations (ionized). The uncharged form is lipid soluble, enabling it to diffuse through tissues and across nerve membranes, which the charged form cannot do. The ratio of uncharged to charged forms depends on the pH of the medium (vial solution or tissue milieu) and on the p$K$a of the specific agent. The p$K$a is the pH at which 50% of the solution is in the uncharged form, and 50% is in the charged form. Because the p$K$a is constant for a specific agent, the relative proportion of these forms is dependent on the pH of the solution in accordance with the Henderson-Hasselbalch equation:

$$pH = pK_a + \log [\text{uncharged}]/[\text{charged}]$$

When the pH of the solution or tissue decreases, a given agent exists more in its ionized, charged form; conversely, when a pH increases, the agent exists more in its nonionized, uncharged form. Because the nonionized portion is the form of drug that can diffuse through tissues and nerves, manipulation

| TABLE 31-1 -- pH and Additives of Amide Local Anesthetics | | | |

of the pH of the solution is a useful tool for the physician (see Factors Affecting Neural Blockade).

Local anesthetic agents are available in plain solution (i.e., without epinephrine), both in single-dose vials or ampules and in multidose vials. For most agents the pH is >5. Multidose vials contain methylparaben as the antibacterial preservative. Local anesthetics also are available premixed with epinephrine and are marketed in single-dose or multidose vials. They contain an antioxidant (sodium bisulfite or sodium metabisulfite) to prevent deactivation of the vasoconstrictor. These solutions must be adjusted to a more acid pH--approximately 3.5 to 4.0--to maintain the stability of epinephrine and its antioxidant. As with plain solutions, multidose anesthetic vials containing epinephrine also contain methylparaben (Table 31-1) .

How an anesthetic is supplied has several implications. First, the lower pH of epinephrine-containing solutions may both make the agent more painful on infiltration and may increase its ionized concentration, thereby delaying its onset. Adding epinephrine to plain solutions just before use does not change the pH of the solution and is reasonable for the physician to do if pain or onset time becomes an issue in a given patient. Second, the additive methylparaben found in multidose vials has been implicated in many allergic reactions. Understanding this fact helps when dealing with patients who claim to be "allergic" to local anesthetics.

## Nerve Structure and Impulse Transmission

### Functional and Structural Components of a Peripheral Nerve

The functional unit is the nerve fiber, which in its practical definition includes the nerve axon and its surrounding Schwann cell sheath. Two distinct arrangements of this nerve sheath are recognized (Fig. 31-1) (Figure Not Available) : (1) unmyelinated nerve fibers have a single Schwann cell surrounding several axons, and (2) myelinated nerve fibers have a Schwann cell wrapped around a single axon, forming a myelin sheath. Junctions between sheaths along the axon are called *nodes of Ranvier*; they contain sodium channels necessary for depolarization. As myelin sheath thickness increases from autonomic to sensory to motor fibers, the nodes of Ranvier with their sodium channels are spaced farther apart.

The most important structure affecting nerve impulse transmission is the axon membrane (Fig. 31-2) (Figure Not Available) . The membrane is composed of a double layer of phospholipid into which are embedded protein molecules that serve as channels

containing pores for the movement of ions into and out of the cell. Most pores have a filter that allows for ion-specific movement, a gate that regulates the passage of ions, and a sensor mechanism that opens or closes the gate.

Bundles of nerve fibers (Fig. 31-3) (Figure Not Available) are embedded in collagen fibrils called *endoneurium* and are surrounded by a cellular layer, the *perineurium*. The perineurium functions as a diffusion barrier and maintains the composition of extracellular fluid around the nerve fibers. Surrounding the entire structure is the outer layer of a peripheral nerve, the *epineurium*, which is composed of areolar connective tissue.

**The Nerve Impulse and Its Transmission**

At rest, the inside of a nerve fiber, or axoplasm, is negative (-70 mV) compared with the outside. This resting potential is the net result of the marked differences in ionic concentrations on each side of the axonal membrane and the forces that tend to maintain that difference. Specifically, there is a surplus of sodium extracellularly and of potassium intracellularly. The sodium channel is closed, preventing these ions from moving along their concentration gradient (out in). Although potassium can leave the cell to follow its concentration gradient (in out), it is prevented from doing so completely because of the need to maintain electrical

**Figure 31-3** (Figure Not Available) Cross section of peripheral nerve. *(From Wildsmith JAW: Peripheral nerve and local anesthetic drugs. Br J Anaesth 58:692, 1986. Reproduced by permission.)*

neutrality inside the cell. Potassium reaches an equilibrium between its concentration gradient and the electrochemical gradient, thus creating the negative resting potential.

When a nerve is excited, the sodium channel opens. At first, a slow influx of sodium ions occurs, but after a critical threshold is reached, sodium enters the cell rapidly, following the electrochemical gradients and its own concentration gradient (depolarization). The influx of sodium is halted when the membrane potential reaches +20 mV, because the inward concentration gradient for sodium is balanced by the outward electrochemical gradient. The sodium channels then close, but potassium continues to move out until the resting potential is again achieved (repolarization). When the excitation process has been completed and the nerve cell is electrically quiescent, the relative excess of sodium inside the cell and potassium outside the cell is then readjusted by the adenosine triphosphate (ATP)-dependent sodium-potassium pump.

During this process, known as the *action potential*, depolarization of a portion of the nerve causes a current to flow along the adjacent nerve fiber. This current makes the membrane potential less negative and actuates the sensor to open the next sodium channel. The action potential cycle is repeated, thereby propagating the impulse. Nerve conduction is essentially unidirectional because in the segment just depolarized (1) the sodium channel is not only closed but inactivated as well, and (2) delayed closure of specific potassium channels prevents the critical threshold from being reached. In unmyelinated nerve fibers, an impulse spreads continuously down the axon. In myelinated nerve fibers, sodium channels are situated at the nodes of Ranvier, and

current flows from node to node, causing intervening segments to depolarize at once. This saltatory conduction accounts for the faster rate of impulse transmission in myelinated fibers.

## Mechanism of Action

The way local anesthetic agents produce nerve conduction blockade can be explored practically by discussing 3 related concepts: (1) the active form of the agent responsible, (2) the physiologic basis for blockade, and (3) the method by which this process is accomplished.

### The Active Form

An anesthetic solution exists in uncharged and charged forms, with the concentration of the uncharged form increasing in more alkaline milieus. It is only this uncharged (lipid-soluble) form that can cross tissue and membrane barriers. Once the agent is through a barrier, the uncharged form re-equilibrates into uncharged and charged forms, the proportion of which again depends on the prevailing pH.

Because local anesthetics were found to be more effective in alkaline solutions, it was originally thought that the uncharged form was responsible for conduction blockade. However, the increased effectiveness of alkaline solutions is currently believed to be due to increased agent penetration through tissue barriers, while the cationic charged form is responsible for actual blockade. Although both the charged and the uncharged forms contribute to nerve blockade, the charged form predominates for most of the common anesthetic agents.

### The Physiologic Basis for Blockade

Prevention of sodium influx across the nerve membrane is the physiologic basis for conduction blockade. Local anesthetics decrease sodium influx, which decreases the rate of rise and amplitude of depolarization. When sufficient anesthetic is present, the firing threshold will not be reached, thereby preventing the action potential from forming. With no action potential, no impulse can be transmitted, and conduction blockade is achieved. The end result is local anesthesia.

### The Cellular Mechanism of Blockade

The means by which anesthetic agents prevent sodium influx is still not completely understood. It is believed that the cationic charged form blocks the action potential from inside the membrane; the agent enters the sodium channel from the axoplasmic side and binds to a receptor about halfway down the electrical gradient. [4] [5] This "specific receptor" theory is well accepted and is considered the predominant mechanism in preventing sodium influx. However, this theory cannot account for the action of benzocaine or other neutral compounds or the uncharged base form of the common local anesthetics.

In summary (Fig. 31-4) (Figure Not Available) , when a commonly used local anesthetic (other than benzocaine) is applied perineurally, it equilibrates into its uncharged and charged forms based on the tissue pH and agent p$K_a$ . The uncharged lipid-soluble form penetrates tissue, nerve sheath, and nerve membrane to gain access to the axoplasm, wherein it re-equilibrates into both forms. The charged form enters the sodium channel to effect blockade by decreasing sodium influx. The uncharged base is also involved with sodium channel blockade, but the exact nature of this mechanism is unknown.

## Factors Affecting Neuronal Blockade

A local anesthetic's activity profile (onset, potency, duration) and its ability to produce a differential blockade in mixed

nerves are a function of physiochemical properties, the physiologic environment, and, to some extent, manipulation by the physician.

**Onset of Action**

The p$K_a$ of an anesthetic is the primary physiochemical factor that determines onset of action. For a lower p$K_a$ , more of the lipid-soluble uncharged form is present, which thereby increases the penetrating ability and shortens the onset of action (Tables 31-2 and 31-3) . Although in isolated nerve fibers onset of action directly parallels p$K_a$ , additional in vivo physiochemical factors exert an influence. For example, prilocaine and lidocaine have the same p$K_a$ , but lidocaine's onset is faster because of its enhanced ability to penetrate through nonnervous tissue.

The site of administration has significant clinical impact. As the amount of interspersed tissue or the size of the nerve sheath increases, the onset times are prolonged for all agents because of the greater distance that the agent must travel to reach its receptor. The role of p$K_a$ becomes more important as the tissue barrier increases. For example, both lidocaine (p$K_a$ 7.9) and bupivacaine (p$K_a$ 8.1) have comparably rapid onsets (2 to 5 minutes) with subcutaneous (SQ) infiltration. However, with brachial plexus block, the onset times are prolonged, but less so for lidocaine (15 minutes) than for bupivacaine (25 minutes).

The pattern of onset for large nerves is determined by the structural arrangement of fibers. Peripheral (mantle) fibers will be blocked before core fibers. Because mantle fibers innervate more proximal regions, nerve blockade proceeds in a proximal-to-distal progression.

A faster onset time may be created by the addition of sodium bicarbonate to raise the anesthetic solution's pH, which yields a higher concentration of the uncharged lipid-soluble form more rapidly. Increasing the total dose also shortens onset time. This can be accomplished by using a higher concentration of the same volume or a greater volume with the same concentration.

For most procedures performed in the emergency department, it is unnecessary to choose a local anesthetic (or iatrogenically alter its activity) based on onset time, but one must be cognizant of the normal delays to avoid premature additional doses that might prove toxic.

**Potency**

The lipid solubility of an anesthetic is the primary physiochemical factor that determines potency. Lipid solubility refers to an agent's partition coefficient, not the concentration of lipid-soluble form that is present as determined by p$K_a$ or pH. Because the nerve membrane is basically lipid, the more lipophilic an anesthetic, the easier it can pass into the cell and the fewer the molecules that are needed for conduction blockade (see Tables 31-2 and 31-3) .

The relative degree of vasodilation produced by local anesthetics also affects potency. Lidocaine is more lipid soluble than prilocaine or mepivacaine, but it produces more vasodilation, which leads to more rapid vascular absorption. This more rapid absorption decreases the number of molecules available to penetrate the nerve. So although lidocaine is twice as potent as prilocaine or mepivacaine in vitro, it is equipotent in vivo. Another important factor is uptake by adipose tissue. Etidocaine, which in vitro is more potent than bupivacaine, is less so in vivo, because its greater absorption by fat results in fewer molecules being available for conduction blockade.

Although this is not a primary reason for its use, epinephrine, by producing vasoconstriction and making more molecules available to the nerve, increases the depth of anesthesia. Agent concentration also is important. By increasing the concentration of the anesthetic agent, potency is enhanced.

Choosing an anesthetic for its inherent potency is usually not necessary for any given site, because the concentration of an agent may be manipulated to make most drugs equianesthetic. For example, lidocaine, being one fourth as potent as bupivacaine, is usually used at 4 times the concentration (1% to 2% vs 0.25% to 0.5%, respectively). One must be cognizant, however, that for different sites and techniques, different concentrations and volumes of a given agent are needed to produce adequate blockade.

| **TABLE 31-3** -- Physiochemical Properties of Selected Local Anesthetics | | | | | |
|---|---|---|---|---|---|
| **Agent** | **Type** | **Site of Metabolism** | **p$K_a$** | **Lipid Solubility (Partition Coefficient)** | **Protein Binding (%)** |

| | | | | | |
|---|---|---|---|---|---|
| Procaine | Ester | Plasma | 8.9 | Low (0.02) | 6 |
| Chloroprocaine | Ester | Plasma | 8.7 | Low (0.14) | -- |
| Lidocaine | Amide | Liver | 7.9 | Medium (2.9) | 64 |
| Mepivacaine | Amide | Liver | 7.6 | Medium (0.8) | 78 |
| Prilocaine | Amide | Liver | 7.9 | Medium (0.9) | 55 |
| Bupivacaine | Amide | Liver | 8.1 | High (27.5) | 95 |
| Etidocaine | Amide | Liver | 7.7 | High (141.0) | 94 |

**Duration**

The protein binding of an anesthetic primarily determines the duration of action. This is because agents that bind more tightly to the protein receptor remain in the sodium channel longer (see Tables 31-2 and 31-3) . Similar to potency, and for the same reason, the duration of action is inversely influenced by the vasodilation produced by local anesthetics. Prilocaine, which is less protein bound than lidocaine, in vivo produces a longer duration of action because of its lesser degree of vasoactivity. The duration of action also varies with the mode of administration, being shorter when an agent is applied topically than when it is injected into the tissues.

Physicians may *prolong the duration of action by several methods.* Increasing the dose, usually by increasing the concentration, prolongs duration but is limited by the possibility of a toxic reaction and the maximum effective concentration of a drug. Although controversial, raising the pH of the anesthetic solution also has been shown to prolong duration. [6] [7]

The most practical way to increase duration is to use solutions that contain epinephrine. [8] Epinephrine causes vasoconstriction, thereby decreasing systemic absorption, which allows more molecules to reach the nerve. The effect of epinephrine varies according to

the agent. Anesthetics that intrinsically produce more vasodilation (e.g., procaine, lidocaine, mepivacaine) benefit more from epinephrine's vasoconstrictive action. The long-acting, highly lipid-soluble agents (e.g., bupivacaine, etidocaine) are less affected because they are substantially taken up by extradural fat and released slowly. In fact, lidocaine with epinephrine may produce almost as long a duration of action as bupivacaine with epinephrine.

The selection of an agent with a long duration of action should be considered if the procedure is lengthy or if postoperative analgesia is desired. Conversely, a shorter acting agent combined with epinephrine or an alkalinized plain solution could be used. Making a specific choice of anesthetic is discussed later.

# TOPICAL ANESTHESIA

Local anesthetic agents may be applied topically to mucous membranes, skin, and lacerations. There are sufficient differences among these sites to merit a separate discussion of each. Topical anesthesia of the eye is discussed in Chapter 67 .

## Mucous Membranes

### Agents and Properties

Effective anesthesia of the intact mucous membranes of the nose, mouth, throat, tracheobronchial tree, esophagus, and genitourinary tract may be provided by several anesthetics, although tetracaine, lidocaine, and cocaine are the most effective and commonly used agents (Table 31-4) . For intraoral or pharyngeal anesthesia, benzocaine (14% to 20%) is commonly used. The anesthesia produced is superficial and does not relieve pain that originates from submucosal structures.

*Tetracaine* solution is an effective and potent topical agent with a relatively long duration of action. It may be used in concentrations from 0.25% to 1% with a recommended maximum adult dose of 50 mg. However, it has the disadvantage of high toxicity, especially the likelihood of severe cardiovascular toxicity without any preceding central nervous system stimulatory phase.

*Lidocaine* also is an effective topical agent that is marketed in a variety of forms (solutions, jelly, and ointments) and concentrations (2% to 10%). It is perhaps most familiar to emergency physicians as the 2% viscous solution prescribed for inflamed or irritated mucous membranes of the mouth and pharynx. The advantage of familiarity should not obscure the fact that misuse can lead to serious toxicity. Topical lidocaine provides an adequate duration for most procedures, with a maximum safe dose of 250 to 300 mg.

*Cocaine* is an effective, albeit potentially toxic, topical agent. Its use is limited to mucous membrane anesthesia of the upper respiratory tract. Although it is an ester, hepatic metabolism occurs, as does hydrolysis by plasma pseudocholinesterase. Cocaine is the only anesthetic that produces vasoconstriction at clinically useful concentrations. This

major advantage is offset by its susceptibility to abuse and its toxic potential. Absorption is enhanced in the presence of inflammation. Toxic effects occur as a result of both stimulating the central nervous system directly and blocking norepinephrine reuptake in the periphery. It should not be administered to patients who are sensitive to exogenous catecholamines. Clinical manifestations include central nervous system excitement, which culminates in seizures and hyperthermia plus central and peripheral effects that result in hypertension, tachycardia, and ventricular arrhythmias. Acute myocardial infarction has been reported secondary to topical application. [9] Cocaine is commonly used as a 4% solution with a maximum (although variable and controversial) safe dose of 200 mg (2 to 3 mg/kg). Coronary vasoconstriction may occur with a 2-mg/kg dose applied to the nasal

**TABLE 31-4** -- Practical Agents for Emergency Department Use--Mucosal Application

| | | Maximum Dosage * | | | |
| | | | | | |
| Agent | Usual Concentration (%) | Adult (mg) | Pediatric (mg/kg) | Onset (min) | Duration (min) |
| Tetracaine | 0.5 | 50 | 0.75 | 3-8 | 30-60 |
| Lidocaine | 2-10 | 250-300 | 3-4 | 2-5 | 15-45 |
| Cocaine | 4 | 200 | 2-3 | 2-5 | 30-45 |

* These are conservative figures; see text for explanations.
The lower dosage should be used for a maximum safe dose when feasible.

mucosa. Topical cocaine should be used cautiously, if at all, in patients with coronary artery disease.

Among other topical anesthetic agents, dyclonine and benzocaine offer distinct advantages. Dyclonine is a ketone derivative without an ester or amide linkage and

therefore may be useful in patients who are allergic to the common anesthetics. Extensive experience with the topical preparation has shown it to be effective and safe. [10] Dyclonine is marketed in 0.5% and 1.0% solutions, with a maximum adult recommended dose of 300 mg.

*Benzocaine* is an ester that is marketed only in its neutral form and is available in 14% to 20% preparations (Cetacaine, Americaine, Hurricane). Its low water solubility prevents significant penetration of the mucous membranes, making it essentially nontoxic systemically if it is applied to the *intact* mucosa. However, it is not a potent anesthetic; it has a brief duration; and compared with other topicals, it is more allergenic. Benzocaine is usually dispensed in an admixture with other therapeutic ingredients and is clinically effective only at relatively high (>14%) concentrations. Benzocaine is available as a nonprescription gel and liquid (Anbesol, 6.3% to 20%) and is commonly used topically by dentists to produce mucosal anesthesia before intraoral nerve blocks (see Chapter 33) . Adriani and Zepernick recommend this agent for lubricating catheters, airways, endotracheal tubes, and laryngoscopes. [10] In their experience with approximately 150,000 patients, only one adverse reaction (methemoglobinemia) occurred.

Similar to reactions to infiltration anesthesia, toxic reactions to topically applied anesthetics correlate with the peak blood levels that were achieved and not necessarily the dose that was administered. Systemic absorption of a topical agent is more rapid and therefore achieves a higher level than the same dose given by infiltration (Fig. 31-5) (Figure Not Available) ; therefore, the *total dose for a topical anesthetic should be considerably less than that used for infiltration at a given site*. Also, fractionating the total dose into three portions over several minutes effectively reduces peak blood levels.

An important potential adverse reaction with topical anesthesia of the nose, mouth, and pharynx is that inadvertent suppression of the gag reflex, combined with difficulty swallowing, may lead to aspiration. Infection from use of solutions from multidose vials for topical anesthesia of the larynx and trachea has not been substantiated.

**Technique and Precautions**

Emergency physicians often prescribe 2% viscous lidocaine for patients with pharyngitis, stomatitis, dental pain, or other inflammatory or irritative lesions in the oropharynx. The common misconception that topical anesthesia is innocuous may result in poor patient instruction with serious consequences. Several reports of seizures and death from topical lidocaine exist in the literature. [11] [12] Toxic blood levels may occur for several reasons: (1) the anesthetic effect of viscous lidocaine lasts only for 30 to 60 minutes, and patients with recurrent pain may either ignore or be ignorant of the safe dosing interval of 3 hours and medicate themselves more frequently; (2) patients tend to increase each dose to obtain greater relief; and (3) inflammation may increase systemic absorption. In addition, painful oral lesions may last for several days.

Continued medication use allows not only the lidocaine but also its major metabolites, monoethylglycinexylidide (MEGX) and glycinexylidide (GX), to accumulate. Both MEGX and GX are produced from hepatic metabolism of lidocaine and are excreted in the

urine. They possess anesthetic and antiarrhythmic activity and have central nervous system toxicity potential. Although these metabolites are less potent than lidocaine, their elimination half-lives, especially that of GX, are considerably longer. Several investigators regard MEGX and GX to be the causes of central nervous system toxicity with prolonged topical use. [12]

The length of time viscous lidocaine is retained in the mouth and whether the excess is expectorated or swallowed also affect the blood level produced. Expectorating the medication after swishing it in the mouth produces much lower blood levels than either swallowing it after swishing or swallowing it straight. It seems logical that the most hazardous mode of administration would be to retain the solution in the mouth "until absorbed."

Physicians must explain clearly the proper way to use viscous lidocaine and inform patients *not to dose themselves ad libitum*. The recommended maximum adult dose is 300 mg (15 mL of a 2% solution) no more frequently than every 3 hours. When possible, the patient should decrease the dose by using direct cotton swab applications. When gargled or swished in the mouth, application time should be limited to 1 to 2 minutes, and the excess solution should be expectorated. It is reasonable to limit use to 2 or 3 days, especially if swallowing the solution is necessary to obtain relief. Lower doses should be prescribed for patients who have risk factors for decreased clearance (see Systemic Toxic Reactions). Doses for children should be calculated by weight, based on 3 mg/kg. Because infants cannot expectorate well, *viscous lidocaine should not be given for minor oral irritation and teething*. Because anesthesia of the oropharynx can interfere with swallowing and cause aspiration, it is recommended that no food be eaten for 1 hour after application. Special note should be made of the over-the-counter availability of benzocaine, commonly used for toothaches and teething. A gel or liquid (Anbesol) is available in 6.3% to 20% formulations. When used repeatedly in the oral cavity on irritated tissue, significant

absorption may occur, and systemic toxicity, often in the form of methemoglobinemia, may result.

## Intact Skin

### Agents and Uses

Although stratum corneum provides a cutaneous barrier that prevents the commonly marketed aqueous solutions (acid salts) from producing anesthesia, saturated solutions of the bases of local anesthetics are effective on intact skin. Interestingly, when applied topically to *abraded* skin, most anesthesia agents result in peak blood levels similar to those resulting from infiltration (and therefore less than mucosal) in 6 to 10 minutes.

**Lidocaine cream.**

Lubens and coworkers have used 30% lidocaine cream, saturated on a gauze pad adherent to an elastic patch, for a myriad of procedures. [13] Despite its effectiveness,

safety, and painless application, the practicality of its use in an emergency setting is limited. However, Lubens and colleagues report an impressive list of uses, including minor operative procedures (e.g., excision of lesions, incision and drainage of abscesses), lumbar puncture, venipuncture, and allergy testing. [13] In many of these procedures, duration of effect need not be long, so that a shorter application time may be used.

**Tetracaine base patch and Emla cream.**

These agents have been extensively studied and appear to be effective and safe. Their activity profiles make them more applicable to emergency medicine than 30% lidocaine cream. Tetracaine base has been available for several years as a solution or gel, but only recently as a patch preparation. It is effective in crossing the lipid-rich barrier of the stratum corneum because it is highly lipophilic. Emla, which stands for *eutectic mixture of local anesthetics*, was approved in the United States in 1992. It contains 2.5% lidocaine and 2.5% prilocaine in a unique oil-and-water emulsion yielding 5% Emla. The mild lipophilic and hydrophilic properties of the component drugs are greatly increased when mixed together, allowing absorption through intact skin.

Although Emla has been more extensively studied, tetracaine base seems to offer emergency physicians the advantage of being able to obtain effective anesthesia with a shorter application time and a longer duration. [14] For both preparations, shorter onset, increased depth of anesthesia, longer duration, and higher blood levels will vary directly with more application time, use on thinner or inflamed skin, or larger dose. [15] Both preparations also exhibit a reservoir effect [16] whereby, during application, the drug is deposited in the stratum corneum and will continue to diffuse along its concentration gradient, even after it is removed from the skin.

Tetracaine base and Emla are useful in the emergency department for providing anesthesia for the following procedures: venous cannulation, venipuncture, or any needle insertion, including preinfiltration anesthesia and lumbar puncture, a variety of minor surgical procedures, and anesthetization of the tympanic membrane and external auditory canal. In addition, Emla has been used effectively for ulcer debridement. [17]

**Ethyl chloride and Fluori-Methane sprays.**

These topical agents are often used for limited skin incisions (e.g., small abscess drainage). When sprayed onto the skin, these agents evaporate with cooling to the point of freezing. Anesthesia is effective and immediate, but drawbacks include its short duration (only up to 1 minute), potential pain on thawing, and possible lowered resistance to infection and delayed healing. Ethyl chloride spray is highly volatile and should not be used around flames or sparks (e.g., electrical cautery).

## Technique

**Lidocaine cream.**

This 30% cream is saturated on a gauze pad adherent to an elastic patch and placed over the area to be injected or incised during the procedure. [13] Both the high concentration of anesthetic and an occlusive patch are necessary to achieve effective skin penetration. The duration of action varies with the application time. For most procedures, a 45-minute application time is minimum; to achieve a topical anesthetic duration of ½ hour, a 2-hour application is necessary.

**Tetracaine base patch and Emla cream.**

Both agents demonstrate a reservoir effect. Depending on the application time, the physician may see the anesthetic effect increase, or even first begin, many minutes after drug removal. Because of the factors just mentioned, it is not easy to be exact concerning application times and duration. Nevertheless, tetracaine base requires a minimum of 20 to 30 minutes' application time and will produce a several hour duration. Emla requires an application time of 1 to 2 hours for a reported duration of 30 minutes to several hours. Occlusive dressings seem to increase Emla penetration whenever the cream is used. For either drug, using patches is more convenient and causes no loss of effectiveness.

Emla dosage is based on the amount of cream applied, not on the amount of anesthetic. Each gram of Emla cream contains 25 mg of lidocaine and 25 mg of prilocaine. Dosages are given in *grams of cream*, not milligrams of anesthetic. In general, Emla is applied as a thick layer to intact skin under an occlusive dressing for about 1 hour before a procedure. A thick layer approximates 1 to 2 g applied per 10 cm2 . For minor procedures such as needle insertions, apply 2.5 g of Emla over 20 to 25 cm2 for at least 1 hour. When starting IV lines, it may be helpful to prepare 2 sites in case of technical difficulties at the first site. For more painful procedures, apply about 2 g of cream per 10 cm2 for at least 2 hours. The appropriate total dose applied also is determined by the maximum application area (MAA). The MAA is based on the patient's weight as follows: up to 10 kg, MAA = 100 cm2 ; 10 to 20 kg, MAA = 600 cm2 ; over 20 kg, MAA = 2000 cm2 .

**Ethyl chloride and Fluori-Methane sprays.**

The technique of application is that the inverted bottle is held 25 cm from the skin, and a stream of spray is directed along the proposed incision until the area turns white and hard. An incision must be made immediately, because the effect may be fleeting. Some clinicians use these vapocoolant sprays to decrease the pain of an injection of a more traditional local anesthetic such as lidocaine.

**Adverse Events**

General adverse reactions to anesthetic agents are discussed in the Complications section of this chapter.

Tetracaine base is quite safe. Blood concentration of tetracaine is very low after proper

use. In 1 study, [16] approximately 25% of the patients developed cutaneous erythema

at the site of application. This vasodilatory effect may actually be an advantage when starting IV lines or performing venipuncture.

Emla is also quite safe. Although there is a high rate of local skin reactions, these are mild and transient, disappearing 1 to 2 hours after cream removal. Despite the reported successful use of Emla cream on skin ulcers, [17] Powell and colleagues demonstrated an increase in bacterial growth and infection and inflammation rates when used in experimental wounds. [18] The main concern with Emla is methemoglobinemia resulting from the metabolites of prilocaine. Despite occasional reports of this problem, which appears to be due to overdose or other risk factors, [15] the risk of clinically significant methemoglobinemia seems remote when Emla is used properly. It is contraindicated in any infant <3 months of age and in those infants between 3 and 12 months of age who are currently taking methemoglobinemia-inducing drugs (nitrites, sulfonamides, antimalarials, phenobarbital, and acetaminophen). The risk of inducing adverse effects also is increased in patients with anemia, respiratory or cardiovascular disease, glucose-6-phosphate dehydrogenase (G-6-PD) or methemoglobin reductase deficiencies.

Prolonged inhalation of ethyl chloride spray may produce general anesthesia, coma, or cardiorespiratory arrest. Ethyl chloride also is flammable, which precludes its use with electrocautery.

## Lacerations

In 1980, Pryor and colleagues reported their experience with a topical anesthetic solution (tetracaine-Adrenalin-cocaine [TAC]) prior to wound repair. [19] Thus began ongoing controversy concerning the efficacy and safety of this compound. The original formula, used in most subsequent studies, consists of a solution of 0.5% tetracaine, 1:2000 epinephrine (Adrenalin), and 11.8% cocaine. Traditionally, anesthesia is produced by firmly applying a solution-saturated gauze pad or cotton ball directly to the laceration for 10 minutes; the resulting loss of cutaneous sensation is centered about the area of application. The recent advent of a gel formulation for TAC and alternative mixtures of agents promise to improve the ease and safety of topical anesthetic solutions for wound repair in the emergency department.

### Indications and Contraindications

The use of TAC (and related topical wound anesthetics) is generally restricted to young children with wounds <5 cm in length in whom the delay for anesthetic application is acceptable and proper application can be assured. Because of the vasoconstrictor agents (epinephrine and cocaine) in TAC, TAC is generally not used in structures without collateral blood supply (e.g., the digits, the tip of the nose, the pinna of the ear, the penis).

Compared with infiltrative anesthesia, the advantages of TAC include painless

application, no distortion of wound margins, good hemostasis, and good patient and parental acceptance in the pediatric age group. As compelling as the case for TAC may appear, some disadvantages have made its acceptance less than unanimous. TAC appears to be less effective on the trunk and extremities than on the face and scalp and less effective than lidocaine infiltration in these areas. There also is a 10- to 20-minute onset time, [20] which may be a drawback in a busy emergency department. The cocaine component presents many drawbacks, including cost and federal regulations that require storage in a locked cabinet and maintenance of separate written records for 2 years after the drug is dispensed.

Another concern with TAC is that some emergency departments use wound care protocols that advocate wound preparation be done before anesthetic application. Hence, wound preparation would likely be painful and therefore incomplete. Proper cleansing of traumatic injuries and surgical debridement cannot be accomplished without some form of local anesthesia. One approach is to remove large debris and clotted blood to allow for the appropriate application of TAC and then finish wound prep once the wound is properly anesthetized.

Two other oft-mentioned drawbacks may be more theoretical than real. Vasoconstrictor-induced higher infection rates (see Complications) have not been borne out clinically. Also, the argument that the necessary 10-minute application period is time consuming and takes valuable nursing time is partially offset by using the child's caretaker or adhesive paper tape alone (in the older, reliable patient) to hold the solution in place. With the use of gel, it is not necessary for anyone to "hold" the medicine in place, although the application time is still required.

**Agents and Effectiveness**

Three clinical trials directly compared TAC with infiltrative lidocaine. Without specifying wound location, Pryor's group found equal anesthetic effect. [19] Complete anesthesia produced by TAC ranged from 82% to 86%, compared with 83% to 92% for SQ lidocaine. The remaining patients obtained partial anesthesia. Hegenbarth and coworkers and Anderson and associates demonstrated results similar to those of Pryor and colleagues. [21] [22] Furthermore, Hegenbarth and colleagues found TAC to be equal to lidocaine only on the face and scalp, and inferior to it at other locations. Other investigators using different study designs found TAC effectiveness to be equal to or slightly less than seen in earlier studies. More recent studies confirm excellent rates of effectiveness, especially on the face and scalp. [26] [27]

Concerned about potential toxic effects and theoretic vasoconstrictor-induced higher infection rates, several investigators compared TAC with its various components. On the face and scalp, TAC was found to be superior to tetracaine alone, although on nonfacial areas, both produced equally poor results. [23] TAC was found more effective than cocaine alone [25] and more effective than a tetracaine-epinephrine solution in the same dosage ratio. [28]

In 1990, Bonadio and Wagner showed that an epinephrine-cocaine solution (epinephrine 1:2000, cocaine 11.8%) was equal to TAC in effectiveness. [26] Bonadio

and Wagner also found that half-strength TAC (tetracaine 0.25%, epinephrine 1:4000, cocaine 5.9%) achieved excellent results for dermal lacerations of the face, lip, and scalp. [24] Smith and Barry, when comparing three strengths of TAC, found equal effectiveness among them and recommended the lowest strength cocaine formulation (tetracaine 1.0%, epinephrine 1:4000, cocaine 4.0%). [29] Most recently, Schilling and colleagues found that a lidocaine-epinephrine-tetracaine solution (lidocaine 4.0%, epinephrine 1:1000, tetracaine 0.5%) was as effective as TAC. [30] Ernst and colleagues found similar effectiveness to TAC using a slightly different lidocaine-epinephrine-tetracaine solution (lidocaine 4.0%, epinephrine 1:2000,

tetracaine 1.0%). [31] The non-cocaine-containing formulations are generally considered less toxic and have advantages in terms of reduced cost and avoidance of controlled substance precautions during storage.

**Application and Dosage**

Because the topical mixtures noted above (especially TAC) are not innocuous anesthetics, attention must be paid to the technique of application and recommended maximum dose. Unfortunately, there is no uniformly accepted application technique, component composition, or component concentrations.

Generally, topical solutions such as TAC are applied as follows: The wound is placed in a gravity-dependent position, and TAC is carefully instilled to fill the wound cavity; after 3 minutes, a single 2-cm × 2-cm gauze pad or cotton ball saturated with TAC is applied to the wound; the pad should be taped, and the caretaker or nursing personnel should hold it firmly for 15 to 20 minutes. The person holding the gauze should wear latex examination gloves to minimize the risk of cutaneous absorption of the solution. The average dose of TAC solution needed is 2 mL.

Based on the known maximal safe dose of infiltrative tetracaine and mucosal application of cocaine and an estimate of solution absorption onto the applicator, Hegenbarth and colleagues estimated the maximum safe dose of full-strength TAC to be 0.09 mL/kg. [21] Other useful estimates for maximum topical doses are tetracaine, 50 mg, and cocaine, 150 to 300 mg. The key to safety is to *avoid TAC on mucosal surfaces or in areas in which sniffing or swallowing may accidentally occur*. Topical mucosal anesthesia is discussed elsewhere in this chapter.

One can prepare an epinephrine-cocaine gel by adding 0.15 g of methylcellulose to 1.5 mL of epinephrine-cocaine solution. The mixture is stirred thoroughly for a minute or two until a gel consistency is obtained. The gel is applied as follows: After sterile preparation, the wound is placed in a gravity-dependent position, and the gel is applied by a cotton-tipped swab to coat the entire wound cavity and margins. The wound is allowed to stand for 15 to 20 minutes and then is thoroughly washed to remove the gel from the wound cavity. In Bonadio and Wagner's study, the average dose used was 0.35 mL of gel containing only 40 mg of cocaine. [27]

**Adverse Events**

Mucosal application may lead to significant systemic toxicity, and fatalities have been reported following this application mode. Even after nonmucosal TAC use, cocaine levels appear in the blood (tetracaine does not) and cocaine metabolites appear in the urine in the majority of patients, [32] [33] although these levels are generally not clinically significant.

Gel formulations of TAC tend to stay in the wound and reduce the risk of solution runoff onto mucosal surfaces. There is no need to use a gauze pad to apply the medication in gel formulation or to hold it in place. Since the entire applied dose will stay in the wound, with little absorption, when an overlying gauze is incorporated, a lower dose generally can be used. Gel also provides a more uniform application to tissues improving anesthetic effectiveness.

Ischemic complications from applying vasoconstrictors to tissues containing end arteries may occur. Therefore, TAC should be avoided on the digits, the tip of the nose, the penis, and the pinna. TAC should be used with caution, if at all, in patients with coronary artery disease, uncontrolled hypertension, seizures, and peripheral vascular disease. Any patient with a decreased plasma cholinesterase level is at increased risk for systemic toxic effects (see Complications).

# INFILTRATION ANESTHESIA

Infiltration anesthesia involves injection of an anesthetic agent directly into the tissue prior to surgical manipulation. Field block anesthesia also may be considered a form of infiltration anesthesia, particularly because the useful agents, concentrations, and recommended maximum dosages are the same. A field block involves an SQ injection of an agent in such a manner as to create a field of anesthesia around the operative site. The injection is made proximal to or surrounding the area to be manipulated.

**Indications and Contraindications**

Infiltration anesthesia is indicated whenever good operative conditions can be obtained by using this technique. It may be used for the majority of minor surgical procedures such as excision of skin lesions, incision of abscesses, and suturing of wounds. An advantage of infiltration over nerve block and general anesthesia is that it is considered both quicker and safer. Local infiltration also can provide hemostasis, both by direct distention of tissue and by the concurrent use of epinephrine.

The major disadvantage of local infiltration, when compared with nerve blocks, is that a relatively large dose of drug is needed to anesthetize a relatively small area. For extensive wounds, the amount of anesthetic required may risk systemic toxicity. However, the maximum allowable volume can be increased by adding epinephrine, by using a lower concentration of anesthetic agent, or by doing both (Table 31-5) . When large volumes are anticipated and a nerve block is anatomically feasible, the nerve

block may be preferred. Infiltration should be avoided for large procedures in small children and in apprehensive patients, especially those with prior adverse reactions (whether vasovagal or otherwise). Local infiltration also distorts the tissues that will be incised or repaired and may not be desirable in areas requiring precise alignment (e.g., some lip repairs).

## Choice of Agent

Local anesthetic agents most frequently used for infiltration are 0.5% to 1.0% lidocaine, 0.5 to 1.0% procaine, and

| TABLE 31-5 -- Maximum Allowable Volume (Adults) | | | |
|---|---|---|---|
| **Agent** | **Concentration (%)** | **Maximum * Safe Dose (mg)** | **Maximum Volume (mL)** |
| Lidocaine | 0.5 | 300 | 60 |
| | 1.0 | 300 | 30 |
| Bupivacaine | 0.25 | 175 | 70 |
| Lidocaine-epinephrine | 0.5 | 500 | 100 |
| | 1.0 | 500 | 50 |
| Bupivacaine-epinephrine | 0.25 | 225 | 90 |

* Some physicians recommend 400 mg as the maximum safe dose for bupivacaine.

**TABLE 31-6** -- Practical Agents for Emergency Department Use--Local Infiltration

| Agent | Concentration (%) | Maximum Dose * | | Onset (min) | Duration |
| --- | --- | --- | --- | --- | --- |
| | | Adult (mg) | Pediatric (mg/kg) | | |
| Procaine | 0.5-1.0 | 500 § (600) | 7.0 (9) | 2-5 | 15-45 min |
| Lidocaine | 0.5-1.0 | 300 (500) | 4.5 (7) ‖ | 2-5 | 1-2 hr |
| Bupivacaine | 0.25 | 175 (225) | 2.0 (3) ¶ | 2-5 | 4-8 hr |

\* These are conservative figures; see text for explanation.
Higher dose for solutions containing epinephrine is in parentheses.
These values are for the agent alone; they can be extended considerably with the addition of epinephrine.
§ Some authorities recommend up to 1000 mg or 14 mg/kg for procaine.
‖ Some authorities recommend up to 7 mg/kg for plain lidocaine in children older than 1 year.
¶ Because of lack of clinical trial experience, drug companies do not recommend the use of bupivacaine in children under the age of 12 years.

0.25% bupivacaine (Table 31-6) . Lidocaine has been the agent most commonly used because of its excellent activity profile, low allergenicity and toxicity, user familiarity, and ready availability. Procaine is useful for patients who are allergic to amide anesthetics. Because of its prolonged duration, bupivacaine is considered by some physicians to be the preferred anesthetic, especially when postoperative analgesia is desired, for prolonged procedures, or even for short procedures that may be interrupted in a busy emergency department.

A comparison of equianesthetic doses of lidocaine and bupivacaine for infiltration anesthesia (Table 31-7) reveals that the duration of action is the major difference between the 2 agents. For the majority of emergency department procedures, it is not necessary to extend the duration of anesthesia beyond 1 hour. Plain lidocaine would therefore seem to be a logical anesthesia choice. However, after laceration repair, patients experience a moderate amount of pain when the lidocaine wears off in about 1 hour. [34] Bupivacaine was demonstrated to reduce this pain following laceration repair for at least 6 hours. This benefit of a prolonged duration of anesthesia must be weighed against the hazards of injury to an unprotected limb or the annoyance of prolonged

numbness to patients who have had simple surgical procedures.

A prolonged duration of anesthesia can be achieved by adding epinephrine, sodium bicarbonate, or both to lidocaine (see Duration) or by using bupivacaine. Advantages of epinephrine are that it provides excellent wound hemostasis and slows systemic absorption. This latter property decreases the peak blood level, thereby decreasing the potential for a toxic reaction, or, conversely, it allows a greater volume of agent to be used for extensive lacerations. The major disadvantage of epinephrine is the theoretical damage to host defenses (Table 31-8) . Adding bicarbonate decreases the pain of administration, but such an addition usually entails bedside preparation (see subsequent discussion). Bupivacaine, if used with due caution, is safe and easy to use. The deciding factors are many, but some logical choices are as follows:

> For a wound with excessive bleeding: lidocaine with epinephrine
>
> For an apprehensive patient: lidocaine with sodium bicarbonate
>
> For anticipated prolonged postprocedure pain: bupivacaine.

## Equipment

The pain of injection can be reduced by use of small-gauge needles. Ideally, a 30-ga needle should be used if injection is made through the skin. If the injection is made through the cut edges of the wound, a 25- to 27-ga needle should suffice. A small-gauge needle also helps slow the rate of injection and reduce the rate of tissue distention. A 10-mL syringe is recommended both for its ease of handling and for the relatively slow rate of injection it allows.

## Technique

Once an agent has been chosen, proper technique of administration should be used to minimize pain, prevent bacterial spread, and avoid intravascular injection.

| TABLE 31-7 -- Comparison of 1% Lidocaine (L) and 0.25% Bupivacaine (B)--Infiltration Anesthesia | | | |
|---|---|---|---|
| | **Lidocaine** | **Bupivacaine** | **Advantage** |

* Based on laboratory studies.
For example, in patients taking MAO inhibitors.

**Buffering**

For a given anesthetic agent, lowering the pH by adding epinephrine increases pain, whereas raising the pH by adding sodium bicarbonate decreases pain dramatically. However, it is probable that pH per se is not the sole factor. It has been shown that the pain produced by various agents does not correlate strictly with the pH. For instance, although bupivacaine (pH 5.5) is more painful than lidocaine (pH 6.5), chloroprocaine (pH 3.4) is less painful than bupivacaine, and procaine (pH 4.3) is less painful than lidocaine. Sodium bicarbonate probably works by increasing the ratio of nonionized to ionized molecules, which either renders the pain receptors less sensitive or causes a more rapid diffusion of solution into the nerve and hence a shorter time to anesthetic onset.

To alkalinize lidocaine, 1 mL of sodium bicarbonate (8.4%, 1 mmol/mL) is added to every 10 mL of anesthetic solution. Unfortunately, as the pH of the solution is raised, the anesthetic becomes unstable and has a decreased shelf life. Therefore, it was initially recommended that buffered lidocaine be prepared just prior to use to avoid precipitation and degradation. However, buffered lidocaine retains its effectiveness for 1 week, and refrigeration may further increase its shelf life. [35] [36] Bicarbonate may be combined with plain lidocaine for both infiltrative anesthesia [37] [38] and digital nerve blocks. [39] In one volunteer study, sodium bicarbonate also was combined with lidocaine with epinephrine, with good effect. [36]

Sodium bicarbonate also can be added to bupivacaine, but the tendency for the solution to precipitate is great as the pH rises. Precipitation also directly varies with the concentration of bupivacaine and the time since mixture. Cheney and colleagues showed that 0.05 mL of 8.4% sodium bicarbonate (measured in a tuberculin syringe)

could be mixed with 10 mL of 0.5% bupivacaine without precipitation. [40] However, extrapolating data from another study, [41] this solution would need to be used within 5 minutes to avoid precipitation. Since the advantage of using bupivacaine is to prolong the duration of anesthesia, and this effect also can be accomplished somewhat by using buffered lidocaine (plain or with epinephrine), it seems impractical at this time to risk precipitation by "buffering" bupivacaine.

### Warming

Warming an anesthetic to body temperature (37 to 42 °C) reduces the pain of infiltration. [42] [43] However, Bartfield and colleagues, using lidocaine warmed to 38.9 °C, found that the warmed lidocaine was somewhat more painful than room temperature buffered lidocaine during intradermal injection. [44] Interestingly, Brogan and colleagues, using lidocaine warmed to 37 °C, found the warmed lidocaine and room-temperature buffered lidocaine to be equivalent during wound infiltration. [45] Neither study found a synergistic effect with combined warming and buffering. Martin and associates also found warmed (37 °C) lidocaine to be no less painful than buffered lidocaine. [46] Anesthetic solutions can be warmed in a baby-food warmer with thermostatic temperature control or in an IV solution warmer. Warming is not believed to adversely affect shelf life of the local anesthetic.

### Injection

Placement of the injection should be subdermal to minimize needle puncture pain and the tissue distention that occurs with intradermal placement. Placing the needle "up to the hub" and injecting while withdrawing along the just-created subdermal tunnel also minimizes distention. After an initial injection, rather than totally withdrawing the needle from the tissue, the needle may be redirected along another path to lessen the number of punctures. Slowly injecting the smallest volume necessary also helps to reduce pain.

Bierman described a technique of patient distraction by applying light pressure to alternate sides of the wound with one's fingers and repeated ambiguous questioning about feeling the light pressure rather than the ongoing wound injection. [47] A school-age child can be asked to count backward or say the "ABCs" as a form of distraction during injection.

Because the patient barely feels a needle placed subcutaneously and skin puncture is often quite painful, ideally, all *wound injections should be made through the wound edge and not via a skin puncture* (Fig. 31-6) . [48] Concern about spreading infection by passing a needle through a fresh wound edge has not been substantiated clinically. However, in the case of a grossly contaminated wound, some clinicians may choose to inject the anesthetic through intact skin.

Preventing a systemic toxic reaction is best accomplished by avoiding an intravascular injection. However, for infiltration anesthesia with small-gauge needles, aspiration is usually unnecessary unless the injection is deeper than the SQ area or the area to be

injected contains many large vessels.

## SPECIAL CONSIDERATIONS

There are many applications of infiltration anesthesia in the emergency department, but the following special cases deserve separate mention.

### Hematoma Block

Hematoma block has been used for many years to provide anesthesia for reduction of fractures, particularly of the distal forearm and hand. Its popularity has waned somewhat because of the fear of introducing infection at the fracture site and its limited efficacy. Although several studies show the hematoma block to be safe, the anesthesia it provides is not as good as that provided by the Bier block. [49] [50] However, there are several reasons to retain this technique. The procedure is simple and quick to perform and does not require additional personnel. There is no need to wait for an anesthesiologist or for the patient to digest a meal, as when general anesthesia is used. A lower dose of anesthetic agent is required compared with that required for the Bier block (see Chapter 34) . Lastly, it is useful when the Bier block and general anesthesia are contraindicated.

This simple technique involves preparing the skin over the fracture site, inserting the needle into the hematoma (confirmed by aspirating blood), and slowly injecting from 5 to 15 mL of plain 1% lidocaine or 5 to 10 mL of plain 2% lidocaine, depending on the fracture site, into the fracture cavity and around the adjacent periosteum. Onset of adequate anesthesia occurs in about 5 minutes and may last for several hours. This procedure should not be performed through dirty skin, into open fractures, or in small children.

### Intra-articular Anesthesia

The history and physical examination of an acutely traumatized knee may underestimate the severity of an injury. Instillation of 5 mL of 1% lidocaine after joint aspiration may help to relieve pain and facilitate examination, but its use is not routinely recommended. [51] Spasm and apprehension are often not relieved by local anesthesia, and the occasional knowledge gained usually does not influence the treatment plan. Intra-articular anesthesia of the knee has no effect on gait pattern or joint proprioception. [52] Therefore, if otherwise indicated, postprocedure weight bearing may be allowed without fear of producing or increasing injury. Intra-articular anesthesia may enhance elbow use following aspiration of a hemarthrosis associated with a radial head fracture. [53] The technique of administration is analogous to arthrocentesis (see Chapter 57) .

### Intrapleural Anesthesia

**Indications**

Intrapleural anesthesia is a relatively new procedure with applicability to emergency medicine. This technique introduces local anesthetic into the pleural space (i.e., between the parietal and visceral pleura) through an epidural catheter. The anesthetic also can be introduced through a previously placed chest tube. The technique has been used to provide relief for several conditions, primarily postthoracotomy pain; postcholecystectomy pain; and, most importantly for emergency

physicians, posttraumatic chest pain (i.e., rib fractures, pneumothorax, hemothorax). This procedure is useful not only for pain relief, but also for allowing the patient to turn, cough, and deep breathe, thereby helping to prevent atelectasis and pneumonia.

Although not unanimous, most studies show that intrapleural anesthesia is effective in providing analgesia. [54] [55] Possibly correctable reasons thought responsible for less than satisfactory results in some studies include dilution of anesthetic by blood in the pleural cavity, inadequate dosing, malposition of the catheter tip, malposition of the patient after injection, and loss of anesthetic through a previously placed chest tube.

Concern has been raised that intrapleural anesthesia may create a level of anesthesia below the umbilicus and make posttraumatic abdominal examinations unreliable. Until this issue is clarified, it seems prudent to rule out intra-abdominal injury before intrapleural anesthesia is used. [56]

**Technique**

If a chest tube is in place, it is preferable to inject anesthesia into the pleural space via the chest tube. Theoretically, the tube should be clamped for 10 to 15 minutes to allow the anesthetic to diffuse. When the tube cannot be taken off suction, or if no tube is present, the local anesthetic is injected percutaneously. The percutaneous method as described by Stromskag and colleagues is presented. [57] With the patient in the lateral position (with the affected side up), a 16-ga Tuohy needle is placed 8 to 10 cm from the posterior midline in the 8th intercostal space. The needle is angled at 30° to 40° to the skin, aimed medially, bevelled upward, and directed just above the rib. After perforating the posterior intercostal membrane (felt as a distinct resistance), the stylet is removed, and a well-wetted, air-filled glass syringe is attached to the Tuohy needle. The needle is advanced until it enters the pleural space, which is denoted by the plunger being drawn down the syringe due to the negative pressure created during inspiration. The syringe is then removed, and an epidural catheter is introduced 5 to 6 cm into the pleural space. The Tuohy needle is removed, a chest radiograph is taken to confirm proper position, and the catheter is secured.

The most commonly used anesthetic and dose is 20 mL of bupivacaine 0.5%. A repeat dose every 8 hours has been shown safe. [58] What position the patient should be in during or after the injection of anesthetic or whether the chest tube, if one is in place, should be clamped, taken off suction, elevated, or left alone are questions not yet fully answered.

The solution presumably diffuses from the pleural space "back" through the parietal pleura and the intercostal muscle to reach the intercostal spaces, where it blocks the intercostal nerves. The level of anesthesia can extend from T2 to T12 and involve skin, chest and abdominal wall, and, potentially, the viscera if the visceral afferent fibers are blocked at the sympathetic chain in the paravertebral gutter.

Although not yet a consistently proven or a completely standardized technique, intrapleural anesthesia offers promise for patients and is a potentially valuable procedure for the emergency physician.

### Xiphodynia

Patients may complain of epigastric or lower thoracic discomfort which is completely or nearly completely reproduced with light xiphoid pressure. This painful condition may be preceded by prolonged coughing, retching, or muscular exertion. Local infiltration of the tender area with 5 to 7 mL of local anesthetic solution (1% lidocaine or 0.5% bupivacaine) using a 25- or 27-ga needle will generally produce considerable improvement in the condition. [59] Some clinicians incorporate a steroid agent with the anesthetic (e.g., 80 mg triamcinolone) for a protracted anti-inflammatory effect. The xiphoid should be easily palpable and generally lies less than 2 cm below the skin surface. Should deeper penetration be required or the patient complain of new pain or respiratory distress following the procedure, an upright chest radiograph is recommended to rule out an inadvertent pneumothorax. Diagnostic injection of the xiphoid process should follow standard clinical evaluation for chest and abdominal discomfort.

## COMPLICATIONS

### Local Anesthetic Effect on Wounds

In addition to producing neural blockade, local anesthetics also have potential effects on wound healing and wound infection.

#### Wound Healing

Local anesthetics produce cytotoxic effects on cell structure and function in a dose- and time-related manner. These effects, demonstrated at doses well below those used clinically, involve fibroblasts more than nervous tissue. Collagen synthesis is inhibited by lidocaine and bupivacaine. [60] Morris and Tracey found that lidocaine in increasing concentrations progressively reduced the tensile strength of wounds. [61] Epinephrine added to 1% and 2% concentrations of lidocaine further reduced tensile strength, but when epinephrine was added to distilled water or to 0.5% lidocaine, it had little effect. Several conclusions appear to be clinically relevant:

Although it may have a delayed anesthetic onset, lidocaine 0.5% solution, without

epinephrine if possible, may be best for wound strength.

When possible, local anesthetics should be avoided in poorly healing wounds, e.g., leg ulcers, or where fast healing is essential.

Local anesthetics in high concentrations might help prevent excessive scarring in patients prone to keloids or hypertrophic scars.

Eriksson and colleagues found that lidocaine reduces the inflammatory response in wounds by decreasing the number of white cells and their metabolic activity. [62] While an inflammatory response may be beneficial in a contaminated wound, it can be detrimental in a sterile wound because of the tissue toxicity that is created by the release of superoxide anions, lysosomal enzymes, thromboxanes, leukotrienes, and interleukins.

**Wound Infection**

Although not generally appreciated, it has long been known that local anesthetics possess antimicrobial activity in vitro. Lidocaine and procaine at 2% concentrations--and, to a lesser extent, at lower concentrations--have been shown to inhibit the culture growth of most gram-negative organisms, with only *Pseudomonas aeruginosa* being particularly resistant.

[63] Gram-positive isolates also were significantly affected by lidocaine and, to a lesser extent, by procaine. A more recent study [64] supports this contention by showing excellent inhibition of bacterial growth by lidocaine 2% and bupivacaine 0.5%, but much less inhibition as anesthetic concentration is lowered to lidocaine 1% and bupivacaine 0.125%. Administering anesthetics before obtaining culture material, including injecting a joint prior to arthrocentesis, may give false-negative culture results and should be avoided if possible. This effect also may be significant in obtaining wound cultures when anesthetic ointments have been previously applied. Furthermore, it has been shown [65] that adding sodium bicarbonate to lidocaine greatly enhances its inhibitory effect on bacteria. Although local anesthetics can interfere with culture testing, several studies show that, by themselves, local anesthetics do not appear to alter the incidence of wound infection.

Epinephrine appears to exert a deleterious effect on host defenses, at least in animal models. Studies with infiltrative and topically applied epinephrine solutions in iatrogenically contaminated animal wounds show an increased potential for infection. [67] [68] Possibly, epinephrine-induced vasoconstriction contributes to tissue hypoxia, which has been shown to retard the killing of *Staphylococcus aureus* by leukocytes, and to a reduction in leukocyte migration into the tissue. [69] Although it has been recommended that solutions containing epinephrine not be used because of the potential enhancement of wound infection, most *clinical* studies using topical anesthesia with vasoconstrictor properties (e.g., tetracaine, epinephrine, and cocaine mixtures) have not demonstrated significantly increased infection rates.

## Local Injuries

Injuries may rarely result from direct application of an anesthetic agent to a nerve or from passage of a needle through soft tissue structures. However, this theoretical concern should not deter the physician from the routine use of local anesthetics for accepted conditions. Factors implicated in transient or persistent neuropathy include acidic solutions, additives, the agent itself, needle trauma, compression from hematomas, and inadvertent injection of neurolytic agents. For example, Born described a series of 49 wrist and metacarpal blocks using bupivacaine in which 8 patients developed a significant neuropathy. [70] He postulated that damage occurred from the trapping of the drug in a confined space and recommended that whenever bupivacaine is used in this situation, it be used in low concentration and volume. Infection, hematomas, and broken needles are other local problems that can be averted by using proper technique. Erroneous needle placement also can produce complications such as pneumothorax during brachial plexus or intercostal block.

It is commonly stated that epinephrine-containing solutions, when injected into tissues containing end arteries, can lead to profound ischemia and gangrene. Areas of special concern include the digits, penis, tip of the nose, or earlobe. This concern is real but is probably overrated when dilute concentrations of epinephrine-containing solutions are used (1:200,000). Some authors state that small quantities of such solutions are usually tolerated on the nose and pinna but advise against their use in the fingertips. [71] Because bupivacaine can be used when prolonged anesthesia is required, and because tourniquets can be used in the digits, there is little need for vasoconstrictors in the digits, although some clinicians use a dilute epinephrine solution there as well (see Chapter 32) . The use of phentolamine (Regitine), which produces postsynaptic alpha-adrenergic blockade, is recommended for vasoconstrictor-induced tissue ischemia. This medication is usually given by local infiltration in a dose of 0.5 to 5.0 mg diluted 1:1 with saline. If local infiltration is ineffective or limited by tension within a tissue compartment, or if the area of vasoconstriction is large, phentolamine may be given by the intra-arterial route. [72]

## Systemic Toxic Reactions

Although they occur in only 0.1% to 0.4% of local anesthetic administrations, systemic toxic reactions are the most frequent serious adverse reactions encountered (Table 31-9) . [73] On administration of a local anesthetic, some of the drug reaches its intended target, and some is absorbed quickly into the systemic circulation. Peak blood levels are generally produced within 30 minutes, with levels then falling because of distribution and elimination.

### High Blood Levels

Systemic toxic reactions generally result from high blood levels of local anesthetic agents. Several factors are important in producing high blood levels, including site and mode of administration, rate, dose and concentration, addition of epinephrine, specific

drug, clearance, maximum safe dosage, and inadvertent intravascular injection.

**Site and mode of administration.**

Comparing the modes of administration for a given dose, the intravascular route produces the highest levels, followed by topical mucosal application, then infiltration (see Fig. 31-5) (Figure Not Available) . Within each mode, the more vascular the site, the more systemic absorption that occurs and the higher the level obtained. The following blocks are arranged in decreasing order of systemic absorption: intercostal, caudal, epidural, brachial plexus, SQ. Therefore, it follows that the site of administration is an important variable in determining the safe dose of an anesthetic. For example, lidocaine 400 mg may produce a nontoxic blood level with abdominal wall SQ infiltration, but when used for an intercostal nerve block, a toxic level would likely result from this dose.

**Rate.**

A more rapid IV injection will produce a higher blood level than a slower injection. Similarly, a single topical application leads to a higher level than a dose that is fractionated over time.

**Dose and concentration.**

The larger the total dose, the higher the peak blood level. It is uncertain whether increasing the concentration while maintaining the total dose by decreasing the volume affects the serum level.

**Addition of epinephrine.**

When infiltrated, epinephrine produces vasoconstriction and reduces systemic absorption, thereby resulting in lower peak blood levels.

**Specific drug.**

When comparing local anesthetics on a milligram-to-milligram basis, the more potent agents are more toxic. Because anesthetics are used in equipotent doses (e.g., 1 mg bupivacaine versus 4 mg lidocaine), they are approximately equitoxic. Blood levels achieved by a particular agent depend on the agent's absorption into, and its distribution and clearance from, the circulation. Agents with high lipid solubility and lower protein binding (etidocaine > bupivacaine > lidocaine > mepivacaine) tend to become

| | | | | **TABLE 31-9** -- Differentiating Systemic Adverse Reactions | | | |
|---|---|---|---|---|

| Findings | Toxic Reactions | Allergy | Vasovagal | Excess Catecholamines, Anxiety *1 (Endogenous), Vasoconstrictor (Exogenous) |
|---|---|---|---|---|
| *Relatively specific signs and symptoms* | Metallic taste Tongue numbness Drowsiness Nystagmus Slurred speech Seizures * Coma Respiratory arrest * | Acute rhinitis Pruritus * Dermatitis Urticaria * Facial swelling Laryngospasm Bronchospasm * | Syncope *2 | Headache Hypertension * Palpitations Apprehension *3 |
| *Overlapping signs and symptoms* | Paresthesia Lightheadedness Tinnitus Tremor Tachypnea Tachycardia (early) Bradycardia * Hypotension * Cardiac arrest | Lightheadedness Tachycardia * Hypotension * Cardiac arrest Nausea and vomiting Dyspnea | Lightheadedness Tinnitus Tachypnea Tachycardia (early) Bradycardia * Hypotension * Diaphoresis | Paresthesia * Lightheadedness * Tremor Tachypnea * Tachycardia * Nausea and vomiting Dyspnea Diaphoresis |

* Denotes common and significant reactions:
1 . Anxiety reaction, including hyperventilation syndrome.
2 . Vasovagal syncope occurs with patient upright; any loss of consciousness in the recumbent position implies a severe toxic or anaphylactic reaction.
3 . Although apprehension is classically associated with anxiety and vasoconstrictor reactions, milder toxic and allergic reactions may cause patient apprehension.

sequestered in tissue and have a slower absorption and hence lower blood levels. Agents with a greater volume of distribution or a faster clearance (etidocaine > lidocaine

> mepivacaine > bupivacaine) also produce lower blood levels. Together these effects produce margins of safety for each anesthetic, with etidocaine having the greatest safety margin, followed by bupivacaine, which is equal to or better than lidocaine.

Esters are difficult to measure in the blood because of their rapid hydrolysis by pseudocholinesterase. As a group, toxicity is inversely proportional to the rate of hydrolysis, such that tetracaine is slowly hydrolyzed and hence most toxic, chloroprocaine is quickly hydrolyzed and least toxic, and procaine falls between the two.

**Clearance.**

Amides are metabolized by the liver, in which the clearance rate is a function of hepatic blood flow and extraction capacity of the liver. Decreased hepatic flow, produced by norepinephrine, propranolol, or general anesthesia, slows clearance and potentially raises drug blood levels. Decreased extraction, associated with congestive heart failure, cirrhosis, or hypothermia, likewise may produce a higher blood level. Hypovolemia, which decreases hepatic flow and hence clearance, does not raise blood levels because it causes an offsetting decrease in absorption.

Decreased clearance of esters, hence an increased risk for toxicity, occurs in patients with either low levels of pseudocholinesterase or an atypical form of pseudocholinesterase. Low levels occur in various disease states, including severe liver disease and renal failure, and in pregnancy. Atypical pseudocholinesterase is an inherited trait, and its presence reduces the hydrolysis rate of procaine to a greater extent than low levels do.

There are significant differences between the pediatric and adult population concerning drug distribution and metabolism. Neonates exhibit both reduced levels of pseudocholinesterase and reduced hepatic metabolism, thus increasing the risk of toxicity. In older children, the effects of increased hepatic metabolism and a relatively larger volume of distribution increase their tolerance for higher doses.

**Maximum safe dosage.**

Before one can appreciate this concept, the principles of dosage calculation must be understood (Table 31-10) . The *maximum safe dose* for a drug may be defined as the dose that produces a blood level of the drug just below the toxic level. Based on the previous discussion, it is obvious that *one* maximum dose for an anesthetic agent appropriate for all patients and all conditions cannot be stated. A maximum safe dose cannot be based solely on the weight of a patient. In fact, in an adult, peak blood levels do not correlate well with weight, because the volume of the drug distribution is relatively constant. [74] [75] However, as an approximation, Arthur and McNicol have recommended basing maximum dosages for children on weight. [76] Plain lidocaine may be used in doses of up to 4.5 mg/kg, whereas the addition of epinephrine allows for a maximum dose of 7 mg/kg. Bupivacaine is not recommended for children under the age of 12. Furthermore, the dose should be modified according to the site and mode of

administration.

Maximum safe doses as stated in package inserts should be used only as guidelines because (1) most of them are derived from animal experiments and are based on absorption data only; (2) levels vary with administration site, use of a vasoconstrictor, and, to some extent, with the health of the patient; (3) they can often be exceeded safely when accurately administered (e.g., bupivacaine with epinephrine has been shown to be safe in peripheral nerve blocks and local infiltration in doses of up to 400 mg); and (4) they may be toxic even within the "safe range" when inadvertently injected IV.

---

**TABLE 31-10** -- Calculation of Anesthetic Doses

Anesthetic solutions are marketed with drug concentration expressed as percentages (e.g., bupivacaine 0.25%, lidocaine 1%). To ascertain the strength of a solution in milligrams per milliliter, consider the following:

A 1% solution is prepared by dissolving 1 g of drug in 100 mL of solution.

Therefore, 1 g/100 mL = 1000 mg/100 mL = 10 mg/mL.

To calculate the strength from the percentage quickly, simply move the decimal point 1 place to the right. Examples:

| | | |
|---|---|---|
| 0.25% = 2.5 mg/mL | (e.g., bupivacaine) | |
| 0.5% = 5 mg/mL | (e.g., tetracaine) | |
| 1% = 10 mg/mL | (e.g., lidocaine) | |

| | | |
|---|---|---|
| 2% = 20 mg/mL | (e.g., viscous lidocaine) | |
| 4% = 40 mg/mL | (e.g., cocaine) | |
| 5% = 50 mg/mL | (e.g., lidocaine ointment) | |
| 20% = 200 mg/mL | (e.g., benzocaine) | |

When combined in an anesthetic solution, epinephrine is usually in a 1:100,000 or 1:200,000 dilution.

0.1 mL of 1:1000 epinephrine in 10 mL anesthetic solution = 1:100,000 dilution = 0.010 mg/mL.

0.1 mL of 1:1000 epinephrine in 20 mL anesthetic solution = 1:200,000 dilution = 0.005 mg/mL.

some examples of epinephrine content:

| | **1:100,000** | **1:200,000** |
|---|---|---|
| 5 mL | 0.050 mg | 0.025 mg |
| 10 mL | 0.100 mg | 0.050 mg |
| 20 mL | 0.200 mg | 0.100 mg |

> Therefore, 50 mL of 1% lidocaine with epinephrine 1:200,000 contains 500 mg lidocaine and 0.25 mg epinephrine.

**Inadvertent intravascular injection.**

Most toxic reactions are caused by inadvertent IV injections of anesthetics whose doses were calculated for their intended extravascular sites. For example, lidocaine 300 mg is a safe infiltrative dose that would likely cause toxicity if directly injected into the bloodstream.

Anesthetics that are injected IV must pass through the lungs before they reach other organs. Lung tissue sequesters a significant amount of drug, which lowers the arterial blood concentration. Therefore, anesthetics that bypass the lungs-- either in cases of inadvertent injection into the carotid or vertebral arteries or in patients with intracardiac right-to-left shunts--can produce central nervous system toxicity at low doses. Similarly, intra-arterial injections about the head or neck are capable of retrograde flow into the cerebral circulation if the injection pressure exceeds the arterial pressure. Because the blood volume in the brain is only about 30 mL at any given moment, even 1 mg of lidocaine injected into the carotid artery can produce toxic concentrations. Also, in a patient with low cardiac output and hypovolemia, preferential cerebral blood flow can enhance central nervous system toxicity.

**Host Factors**

Four factors--hypoxia, acid-base status, protein binding, and concomitant drugs--tend to lower the body's systemic tolerance to local anesthetic agents.

**Hypoxia.**

It was initially thought that local anesthetic overdose produced central nervous system stimulation and subsequent intracellular hypoxia, which then became the key precipitant to all toxic manifestations of the drug. It is now known that hypoxia may enhance anesthetic toxicity, but it is not the primary factor.

**Acid-base status.**

Although studies of metabolic alkalosis have produced conflicting results, acidosis, particularly respiratory acidosis, can increase toxicity. The elevated $CO_2$ produced by respiratory acidosis crosses the blood-brain barrier, where it may act directly on the receptor and indirectly by lowering intracellular pH. This latter property causes more drug to ionize, furthering the block in the sodium channel and increasing the potential for toxicity.

**Protein binding.**

Unbound drug concentration relates more closely to toxic effects than does total drug concentration (bound plus unbound) as measured in the blood. The amount of alpha-acid glycoprotein (AAG), the major plasma protein responsible for binding local anesthetics, is considerably decreased in neonates compared with adults, thereby allowing for a greater percentage of free drug. Arthur and McNicol imply that low AAG levels in neonates are responsible for an increased toxic potential. [76] Tucker lists several disease states that alter AAG levels and protein binding but questions whether they lead to changes in free drug concentration in vivo. [77]

**Concomitant drugs.**

For years, barbiturates were used prophylactically to prevent, and therapeutically to treat, local anesthesia-induced seizures. Although at least the latter purpose proved valid, barbiturates were found to worsen anesthetic-induced apnea and cardiovascular depression. Central nervous system depressants should be used with caution when concern exists for local anesthetic toxicity. Central nervous system stimulants have been shown to increase anesthetic-induced excitability and should be avoided. Mixtures of local anesthetics essentially have an additive effect on toxicity, so if 2 drugs are used at half strength, they produce the same degree of toxicity as if each was used alone at normal strength.

### Recognition of Central Nervous System Toxicity

The earliest manifestation of systemic toxicity is central nervous system stimulation resulting from blockade of inhibitory synapses. Central nervous system depression follows and is produced by direct depression of the medulla, although hypoxia may play a role. Signs and symptoms are dose related. Potential signs and symptoms of central nervous system toxicity, in increasing order with representative plasma lidocaine concentrations in parentheses, are numbness of the tongue, light-headedness, tinnitus (4 mug/mL), visual disturbances (6 mug/mL), muscle twitching (8 mug/mL), convulsions (10 mug/mL), coma (15 mug/mL), and apnea (20 mug/mL). Drowsiness, commonly seen at lower doses with lidocaine, is not associated with bupivacaine or etidocaine. Tetracaine may produce apnea or cardiovascular toxicity without central nervous system manifestations.

### Recognition of Cardiovascular Toxicity

Moderate blood concentrations (e.g., lidocaine, 3 mug/mL) of local anesthetics produce slight increases in cardiac output, heart rate, and arterial pressure because of the effects of direct peripheral vasodilation and central nervous system

stimulation. At concentrations generally well above central nervous system toxicity levels, local anesthetics cause direct myocardial depression, manifesting as hypotension and bradycardia, which can lead to cardiovascular collapse. These agents

also slow electrical conduction leading to reentry phenomenon and various supraventricular and potentially lethal ventricular dysrhythmias (especially with bupivacaine and etidocaine).

**Prevention**

Knowledge of factors contributing to toxicity should guide preventive measures. Esters should be avoided in patients with an atypical form or a quantitative deficiency of pseudocholinesterase. Amides should be used with caution in patients with severe liver disease or congestive heart failure. Maximum safe dosages, based on site, technique, epinephrine use, and patient status, should be observed. Epinephrine should be added whenever possible to decrease the drug absorption rate at vascular sites. Drug concentration can be reduced with saline dilution to increase the volume for administration when a large area must be infiltrated. Frequent aspiration should be performed in areas of high vascularity. However, even a negative aspiration may not prevent IV administration. [78] Therefore, slow infiltration is advised for safety and is also associated with less pain.

**Treatment of Systemic Toxicity**

No physician should perform local anesthesia without the ability to recognize and treat a toxic reaction; this includes having all necessary equipment and drugs readily available and being knowledgeable in their use. Despite taking all possible precautions, toxic reactions still occur, and maintaining a rapport with the patient allows early detection and treatment.

Providing proper oxygenation and ventilation at the earliest sign of a reaction is the cornerstone of treatment. Patients who are alert should be encouraged to moderately hyperventilate to lower the $P_{CO_2}$ and raise the seizure threshold. Likewise, for patients who cannot adequately ventilate, intubation with high-flow oxygen and hyperventilation should be performed. An IV line should be started, and vital signs and cardiac rhythm should be monitored closely.

Seizures are generally self-limited but should be treated if they persist or prevent adequate ventilation. Because respiratory depression secondary to toxicity may follow, low-dose diazepam, 2 to 5 mg, or an ultrashort-acting barbiturate (thiopental or sodium methohexital) is preferred. For seizures that persist, intubation and use of a paralyzing agent are recommended to ensure an effective airway and prevent further lactic acidosis. Beware: if toxicity is caused by an ester, especially if there is an associated pseudocholinesterase problem, succinylcholine will compete with the anesthetic for the pseudocholinesterase and may increase the toxicity of both compounds.

Cardiovascular toxicity manifesting as hypotension and bradycardia should be treated with fluids, leg elevation, alpha- and beta-agonists (epinephrine, ephedrine, or dopamine), or atropine as the need dictates.

Although lidocaine (with diazepam pretreatment) has been shown to be effective for

bupivacaine-induced ventricular dysrhythmias, there is strong theoretical and experimental evidence that bretylium is the antidysrhythmic drug of choice. [79] [80] High doses of atropine and epinephrine can be successful in correcting pulseless idioventricular rhythm. Cardiopulmonary resuscitation, of course, should be instituted when necessary.

## Allergic Reactions

### Allergenic Agents

True allergic reactions are rare, accounting for only 1% to 2% of all adverse reactions, but they are important to recognize because of their serious potential. Ester solutions (procaine, tetracaine), which produce the metabolite para-aminobenzoic acid (PABA), account for the great majority of these reactions. Amide solutions (lidocaine, bupivacaine) are rarely involved, and it is usually the preservative methylparaben (MPB), which is structurally similar to PABA, that is responsible. Hence, although pure esters and pure amides do not cross-react, amides may appear to do so if multidose vials containing MPB are used. Also, patients may manifest an allergic response on first contact to a local anesthetic because of previous sensitization to these agents. MPB is found in creams, ointments, and various cosmetics, and PABA is an ingredient in many sunscreen preparations.

Although cell-mediated delayed reactions manifesting as dermatitis may occur, it is immediate hypersensitivity that most concerns the emergency physician. A spectrum of signs and symptoms may occur, from rhinitis and mild urticaria to bronchospasm, upper airway edema, or full-blown anaphylactic shock. Onset may be immediate, at times even occurring during administration of the agent. Diphenhydramine and SQ epinephrine are useful for mild urticaria and bronchospasm, respectively. IV epinephrine, hydrocortisone, and diphenhydramine may be required for more serious reactions.

The more frequent problem facing emergency physicians is the management of the patient who claims to have a past history of local anesthetic allergy. Indeed, most patients, as well as their physicians, tend to assume that any adverse reaction to a local anesthetic procedure is an allergy. Because allergy is rarely the cause, a careful history and a review of prior records, if available, become crucial in evaluating these patients. The history should attempt to uncover the actual cause of the past reaction and the specific agent involved. Inquiry should be made concerning the exact signs and symptoms, technique of administration, amount of drug used, and how the patient was treated. If an allergic reaction cannot be ruled out and the drug previously used is known, it is often recommended to use an agent from the other class (whether amide or ester). Lidocaine from a dental cartridge does not contain MPB, and if this were the allergenic source, then an ester agent could be used. However, if lidocaine from a multidose vial is implicated, one should not use an ester, because MPB may cross-react with PABA. In this case, it may be safer to use an amide without MPB or to choose an alternative (see below). In most cases the allergen is an ester, and the patient can safely be given an amide without MPB. Single-dose ampules of 1% lidocaine without

MPB, readily obtainable from a resuscitation cart, can be used for this purpose.

However, uncertainty often exists regarding the specific agent involved, and the physician must choose an alternative approach to local anesthesia. If the wounds are extensive and the risk is acceptable, general anesthesia may be used;

conversely, if minimal pain is expected and the procedure is short (e.g., 1 or 2 sutures or staples in the scalp), no anesthesia may be required. Other alternatives include parenteral narcotics, benzodiazepines, nitrous oxide inhalation, or a combination of these. These methods may be useful, but the degree of anesthesia produced is often not sufficient. Antihistamines injected into a wound have been successfully used for many years and represent a good alternative. Local anesthetic efficacy is found in varying degrees in all antihistamines.

**Diphenhydramine**

Several studies demonstrated that 1% diphenhydramine (Benadryl) is as effective as 1% lidocaine for infiltrative anesthesia. [ As long as diphenhydramine is not used at concentrations >1%, potential problems of skin necrosis or significant sedation seem to be rare. *The standard 5% parenteral form should be diluted to 1% for SQ injection* (1 mL drug to 4 mL saline). The duration of action for diphenhydramine is shorter than that for lidocaine but appears to be adequate for most procedures. The injection pain of diphenhydramine exceeds that of lidocaine but can be diminished by reducing the concentration to 0.5%. At this concentration, the effectiveness of this agent on facial wounds is lost. [84] The addition of epinephrine to 0.5% diphenhydramine results in a more painful solution with a shorter duration of action than a standard buffered lidocaine with epinephrine solution. [85]

**Skin Testing**

Skin testing and progressive SQ challenge doses deserve special mention because they appear to be logical and well-studied approaches. Intradermal skin testing with local anesthetics is, at best, controversial. False-positive results are frequently produced by local histamine release secondary to needle trauma, tissue distention, or preservatives in the solution. [86] In addition, a high incidence of false-negative results can occur, and it is questionable whether these low-molecular-weight drugs or their allergenic metabolites are ever capable of eliciting positive responses. [87] Other disadvantages of skin testing include its time-consuming nature and its potential hazard when even minute traces of an allergen may precipitate a serious reaction. SQ challenge testing in graduating doses has been advocated and may well eliminate many false responses, but it does not eliminate the problems of time and hazard. Swanson, recognizing that allergy to pure lidocaine is extremely rare, recommends 0.1 mL as a one-shot intradermal skin test. [88] Although his approach eliminates the time disadvantage, the intradermal placement can still produce false responses. It would seem more reasonable to give this test dose subcutaneously while exercising due caution in the unlikely event that a patient exhibits a serious reaction.

**Summary**

Generally speaking, the optimal approach to the patient with a presumed anesthetic allergy is to determine the specific anesthetic agent associated with a presumed allergic reaction and then use a preservative-free agent from the other class (see above discussion). If the agent is unknown, then one should either use an antihistamine or give 0.1 mL of preservative-free lidocaine as an SQ test dose, proceeding with the full dose if no reaction occurs within 30 minutes. Given the studies mentioned earlier, the prudent choice would seem to be diphenhydramine (Benadryl).

## Catecholamine Reactions

Anxiety and vasoconstrictor (epinephrine) reactions are discussed together, because each produces similar manifestations that are related to elevated catecholamine levels. These reactions, which are difficult to distinguish from each other, are relatively common, although generally not serious.

Excess catecholamine levels produce tachycardia; palpitations; hypertension; apprehension; tremulousness; diaphoresis; tachypnea; pallor; and, on occasion, anginal chest pain. Thus, catecholamine excess may resemble the central nervous system stimulation phase of local anesthetic toxicity.

Catecholamine reactions are usually not caused solely by exogenous epinephrine, because if it is used in its optimal concentration (1:200,000), the maximum safe dose (0.25 mg) is rarely exceeded. However, many patients produce significant endogenous catecholamines secondary to anxiety about the anesthetic approach or upcoming procedure. In this case, even the addition of small amounts of epinephrine could trigger a catecholamine reaction. Therefore, patient preparation should include proper explanation and reassurance to decrease anxiety. Caution also should be exercised in patients who have hyperthyroidism, hypertension, or atherosclerotic cardiovascular disease, but those conditions do not contraindicate the judicious use of epinephrine-containing anesthetics. Epinephrine-containing anesthetics should not be given to patients on monoamine oxidase inhibitors (MAOIs).

Treatment includes stopping further drug administration; observing the patient closely; and administering alpha- and beta-antagonists or benzodiazepine agents, if necessary, to combat severe reactions.

## Vasovagal Reactions

Vasovagal reactions are not uncommon, especially in dental procedures (reported incidence, 2% to 3%), during which the patient is generally in an upright position. The patient initially experiences anxiety when a triggering event, commonly the sight or sensation of needle insertion, causes a loss of sympathetic tone and an increase in vagal tone. The resultant hypotension and bradycardia may lead to syncope. Preparation to decrease patient anxiety and *administration of injections with the patient*

*recumbent* are useful preventive measures. Concomitant cardiac monitoring also may help identify the onset of vagally induced bradycardia when suggested by past history. Treatment consists of laying the patient flat and elevating the legs. Rarely, atropine may be required. Should a patient lose consciousness while in a recumbent position, diagnoses other than vasovagal syncope should be considered, although significant bradycardia, and even complete heart block, may accompany a vagal reaction in the supine patient.

## Miscellaneous Reactions

### Malignant Hyperthermia

There is some concern that amides may produce malignant hyperthermia in susceptible individuals. It is recommended

that esters be used in lieu of amides in patients from families with this genetic abnormality.

### Methemoglobinemia

Despite an excellent safety margin and the fact that many consider it to be the agent of choice for IV regional anesthesia, prilocaine has declined in popularity recently because of its ability to cause methemoglobinemia. [89] The effect is seen when cumulative or single doses exceed 600 mg. In large doses lidocaine also may produce methemoglobinemia.

Benzocaine, a common ingredient in several over-the-counter and prescription topical anesthetics, is well known to produce methemoglobinemia. [90] Although this reaction is infrequent and may occur secondary to a heterozygote enzyme deficiency, it also is known to occur with excessive topical or SQ application in normal individuals, especially children. Methemoglobinemia may rarely occur following the use of benzocaine-containing sprays used to anesthetize the throat (e.g., during endoscopy).

# Chapter 32 - Nerve Blocks of the Thorax and Extremities

**Edwin Dean, Michael Orlinsky**

The use of nerve blocks is an integral part of the practice of emergency medicine. This chapter provides technical guidance for the performance of commonly used nerve blocks.

While virtually every peripheral nerve can be blocked at some point along its course from the spine to the periphery, digital nerve blocks of the fingers and toes are more commonly used than proximal blocks. In a survey of practicing emergency physicians, 99% used digital blocks, 43% used blocks at the wrist, 4% at the elbow, and 4% at the axilla. [1]

Nerve blocks may be underused in the emergency department. Potential applications include femoral blocks for femur fractures, ankle blocks for foot lacerations, intercostal blocks for rib fractures, supraorbital blocks for foreheads traumatized by contact with a windshield or other blunt object, and ear blocks for ear lacerations.

The preparation, technique, choice of anesthetic, precautions, and complications are similar for all nerve blocks and are described in general in the following sections. The clinician is encouraged to use the same basic techniques and precautions for all nerve blocks. Specific precautions unique to a particular nerve block are included with the description of that block; obvious precautions, such as aspiration before

injection when the needle is in close proximity to a vascular structure, are not restated to avoid redundancy.

## GENERAL CONCEPTS

**Indications**

For most of the lacerations and injuries seen in the emergency department, local infiltrative anesthesia is adequate and more efficient than using a nerve block. Local infiltration is quick, reliable, and effective compared with many of the nerve blocks, which tend to require a more extensive setup and have a less reliable and longer onset. Furthermore, those patients who require extensive repair and anesthesia of the entire extremity are often referred to a specialist, who may prefer to examine an unanesthetized limb.

In general, a nerve block is indicated when it will provide advantages over other techniques. Scenarios in which this requirement is met include the following:

When distortion from local infiltration hampers closure (e.g., facial wounds) or

may compromise blood flow (e.g., fingertip)

When anesthesia is required over a large area and multiple injections would be painful, or the large amount of anesthetic needed for local infiltration exceeds the recommended dose

When a nerve block is the most efficacious form of treatment, as in an intercostal block for treating a rib fracture in a patient with chronic obstructive pulmonary disease

When extensive limb surgery or manipulation is required and other options are not available

## Preparation

A brief history, including drug allergies, medications, and systemic illnesses should be taken from the patient. Peripheral vascular, heart, and liver disease increase the risk of severe complications. Monoamine oxidase inhibitors preclude the use of anesthetic agents with epinephrine, as the vasoconstrictor may cause exaggerated cardiac responses in this setting.

### Instructions

The procedure should be explained to the patient, including the pain of the needle insertion, paresthesias that may be felt, and possible complications that may occur. *The possible need for additional anesthetic or alternate procedures if the initial nerve block fails should also be discussed beforehand*. The patient should understand that the additional administration of anesthetic is part of the normal procedure rather than an attempt to correct an incomplete nerve block.

### Equipment

The degree of equipment preparation depends on the extent of the procedure. For a simple digital block, a 10-mL syringe, an 18-ga needle for drawing the solution from the vial, and a 3.75-cm, 25- or 27-ga needle for the nerve block will suffice. Note that the needle sizes given in the text are general recommendations. For most blocks, a needle 2 gauges larger or smaller or 1 cm longer or shorter is adequate.

For more elaborate blocks, the necessary equipment is listed in Table 32-1 . Use of an extension tubing set between the needle and a stopcock syringe assembly facilitates independent needle placement and syringe manipulation. In addition, standard resuscitation equipment for advanced cardiac life support should be readily available any time local anesthetic agents are given.

### Choice of Anesthetic

The factors influencing the choice of anesthetic agent for nerve block are similar to those for local infiltration. In general, most nerve blocks are done for the repair of painful traumatic injuries that are likely to cause pain long after the repair is complete. In such cases, anesthetics with the longest duration of action should be selected to maximize the patient's analgesia. For most of the blocks described in this chapter, 0.25% bupivacaine is suggested as the anesthetic of choice, but equal volumes of 1% lidocaine with epinephrine can be substituted. Care must always be taken to *avoid exceeding* the recommended dosages of anesthetic.

Buffering the anesthetic may lessen the pain of infiltration. Buffered lidocaine is less painful and equally as efficacious as plain lidocaine in digital blocks. [2] Similarly, heating the anesthetic to 37 to 41 °C also reduces the pain of digital blocks (also see Chapter 31) . [3]

### Positioning of the Patient

Ideally, nerve blocks should be performed with the patient in the supine position. This enhances patient comfort and prevents the unexpected vasovagal syncope that may occur when the patient is in an upright position. Vasovagal syncope may be induced from the pain of the injection or "needle phobia." Although this reaction is more common with fair-skinned patients, every patient is at risk for fainting at the site of a needle or during a painful injection.

### Preparation of the Area to Be Blocked

Although the incidence of infection following nerve blocks is minuscule, the field should be prepared in an aseptic fashion before needle puncture. This can be accomplished by swabbing the area with povidone-iodine solution or alcohol and then using standard aseptic injection technique. Sterile drapes and gloves are recommended in addition to aseptic skin preparation for the initiation of blocks that (1) are close to large joints, vessels, and nerves; (2) are located in inherently contaminated areas of the body; or (3) require

simultaneous palpation of the underlying structures while injecting.

**Choosing the Nerves to Block**

Successful anesthesia often requires blocking 2 or more nerves. When deciding which nerves are involved, 2 points must be considered. First, the cutaneous distribution of the various peripheral nerves differs slightly from patient to patient, and second, the sensory innervation of adjacent nerves overlaps to some degree. A liberal margin of error should be used when determining which nerves supply the desired area of anesthesia.

**Locating the Nerve**

Inserting the needle in close proximity to the nerve--that is, "next to" small nerves and "into" the nerve sheath of large nerves--is the essential step in a successful block. When searching for the nerve, its anatomic relationship at the block site can be generalized into 1 of 3 types. First are those sites with good structural landmarks (e.g., prominent bones or tendons) immediately next to the nerve. For example, the digital nerves are reliably found at the 2, 4, 8, and 10 o'clock positions around and just superficial to the proximal phalanx, and the median nerve lies between the palpable palmaris longus and flexor carpi radialis tendons at the proximal crease of the wrist. Second are the sites with easily palpable arteries adjacent to the nerves such as in the axilla and groin. Third are the sites with poor landmarks.

Blocking nerves with good structural or vascular landmarks is straightforward: the landmarks are palpated, the course of the nerve in relation to those landmarks is visualized in the mind's eye, and the needle is inserted in close proximity to the nerve. Paresthesias, as discussed later, may ensure close proximity.

Blocking those nerves with poor landmarks, such as the radial nerve at the elbow, requires skill through practice, some degree of luck, or a nerve stimulator if they are to be blocked consistently.

**Nerve Stimulator**

Despite its sophisticated name, a nerve stimulator is inexpensive and simple to use. With minimal practice, the needle can be placed easily and reliably within a few millimeters of the nerve. The device is simple, consisting of a battery-operated nerve stimulator that delivers current in the range of 0.1 to 0.5 mA, a disposable Teflon-coated needle, and an electrocardiogram pad. One wire electrode from the nerve stimulator is attached to the electrocardiogram pad, which is placed on the limb approximately 10 to 15 cm from the injection site. The other wire electrode is attached to the Teflon-coated needle at its hub. Once inserted into the tissue, the needle tip is electrically active. When in close proximity to the nerve, electric current stimulates the nerve, producing twitching of the muscles supplied by that nerve. For example, when the ulnar nerve is stimulated, the small and ring fingers flex. Anesthetic solution can then be injected into the area at the stimulation site.

**Paresthesia**

When a nerve stimulator is not available, another useful technique to ensure that the needle tip is in close proximity to the nerve is to elicit a paresthesia. By touching and mechanically stimulating the nerve with movement of the needle tip, a tingling sensation or jolt known as a *paresthesia* is felt along the distribution of the nerve.

In practice, the jolt of a true paresthesia is often difficult to distinguish from the "ouch" of a pain-sensitive structure. When blocking proximal nerves of the elbow or axilla, the paresthesia travels far enough away from the injection site that it can be distinguished from locally induced pain. Paresthesias at the level of the hand and wrist are much less

reliably distinguished from pain. In both cases, the paresthesia is a subjective feeling that requires intelligent and cooperative patients who understand what they are expected to feel and who remain relaxed and attentive so that they are able to distinguish an ouch from a jolt. All too often, the patient in pain is willing to tell the physician what the physician wants to hear: the sensation that just made the patient jump was a "paresthesia." Before the procedure, a simple explanation of what the patient should or may feel will facilitate cooperation.

## Injecting the Anesthetic

One strives to ensure that the anesthetic agent is not inadvertently injected into the vessels or nerve bundle. Before injection, the syringe is aspirated to check for blood. If no blood is aspirated, the anesthetic is injected while the extremity is observed for blanching, which suggests intravascular injection. If blanching occurs, the needle should be repositioned before further injection. The technique of syringe aspiration is not necessary when using 25- or 27-ga needles in the proximity of small vessels (e.g., during digital blocks).

The onset and duration of anesthesia are greatly influenced by the proximity of the injected anesthetic to the nerve. Onset is within a few minutes if the anesthetic is in immediate proximity to the nerve. Onset takes longer or may not occur if the anesthetic must diffuse more than 2 to 3 mm, which underscores the importance of locating the nerve before injection.

More anesthetic is required if it must diffuse a large distance to the nerve. A range of suggested volumes of anesthetic is given with each nerve block description. For blocks in which a definite paresthesia is elicited or a nerve stimulator is used, the minimal recommended amount of anesthetic suffices. For many of the blocks of the smaller nerves, paresthesias are not easily elicited, and the anesthetic is placed in the general vicinity of the nerve. For these blocks, or when doubt exists about proximity of the needle to the nerve, larger amounts of anesthetic are recommended. This point cannot be emphasized strongly enough. The difference between a successful and an unsuccessful block may be merely an additional 2 mL of anesthetic. When in doubt, err on the high side of the recommended dosage.

Onset of the anesthetic occurs in 2 to 15 minutes, depending on the distance the anesthetic must diffuse to the nerve. One should wait for 30 minutes before deciding that the block was unsuccessful.

## Complications and Precautions

Complications may result from poor peripheral nerve block technique. General precautions include measures to minimize nerve injury, intravascular injection, and systemic toxicity.

No statistics exist on the complication rate from nerve blocks performed by emergency physicians. Anesthesiologists report rates of less than 1% for blocks of the nerves of the

hand and wrist and up to 10% for axillary blocks. [4] In this study there was no breakdown of serious versus minor complications, although local complications (hematoma and neuropathy) are most common. Generally, infrequently performed blocks, blocks that require high doses of anesthetic, and blocks close to major vascular structures have the higher rates of problems. The technical ability of the practitioner largely determines the outcome.

**Nerve Injury**

Neuritis, an inflammation of the nerve, is the most common nerve injury but overall is a rare complication. [5] [6] The patient may complain of pain and various degrees of nerve dysfunction, including paresthesia or motor or sensory deficit. Most cases are transient and resolve completely. Supportive care and close follow-up are the mainstays of treatment.

Nerve injury can occur secondary to (1) direct trauma from the needle, (2) ischemia due to intraneuronal injection, or (3) chemical irritation from the anesthetic. Proper needle style, positioning, and manipulation minimize direct nerve damage. A short beveled needle should be used and maneuvered so that the bevel is parallel to the longitudinal fibers. Sharp pain or paresthesia indicates that the needle is close to or in the nerve. Excessive needle movement should be avoided when the needle tip is contacting a nerve. Attaching the needle to an IV extension tube reduces needle movement and subsequent nerve damage during syringe plunger manipulation.

Intraneuronal injection may cause nerve ischemia and injury. Elicitation of a paresthesia or severe pain suggests that the needle has made contact with the nerve. *When a paresthesia is elicited, the needle must be withdrawn 1 mm before the anesthetic is injected.* If the paresthesia occurs during injection, the needle must be repositioned. Most neurons are surrounded by a strong perineural sheath through which the nutrient arteries run lengthwise. Injection directly into a nerve sheath may increase the pressure within the nerve and compress the nutrient artery. Impaired blood flow results in nerve ischemia and subsequent paralysis. Intraneuronal injection is often heralded by severe pain, which worsens with further injection and may radiate along the course of innervation. The operator may notice difficulty depressing the syringe plunger. If the needle tip is in proper position, slow injection of the anesthetic should be minimally painful, and the anesthetic should go in without resistance.

Concentrated anesthetics can produce a chemical irritation of the nerve. Therefore, emergency clinicians should use only recommended doses and concentrations of anesthetic (Table 32-2) .

**Intravascular Injection**

Intravascular injection results in both systemic and limb toxicity. Inadvertent intravascular injection produces high blood levels of the anesthetic, with resultant toxicity, as discussed earlier. Particular care must be taken when administering large

amounts of anesthetic in close proximity to large blood vessels.

Intra-arterial injection of anesthetic with epinephrine may cause peripheral vasospasm that further compromises injured tissue. Intravascular anesthetic is not toxic to the

limb itself, although it may produce transient blanching of the skin by displacing blood from the vascular tree. Epinephrine, however, can cause a prolonged vasospasm and subsequent ischemia if it is injected into an artery. Severe epinephrine-induced tissue blanching or vasospasm may be reversed with local or intravascular injection of phentolamine.

Although vasospasm associated with epinephrine in anesthetic solutions has not been observed for nerve blocks, experience in related clinical situations should guide therapy. Roberts and Krisanda used a total of 5 mg of phentolamine infused intra-arterially to reverse arm ischemia following 3 mg of epinephrine inadvertently administered into the brachial artery during cardiac resuscitation. [7] Digital ischemia from inadvertent epinephrine autoinjection has been treated by both proximal "digital block" with 2 mg of phentolamine [8] and by local infiltration at the ischemic site with 1.5 mg of phentolamine. [9]

The route of phentolamine administration may be guided by the clinical situation.

Phentolamine must reach the site of vasospasm. Arterial injection has the advantage of

delivering the medication directly to the spasmed arteries. Local infiltration may be effective for ischemia of a single toe or finger. For larger areas of involvement or in instances where local infiltration is ineffective, intra-arterial injection should be used. A dose of 1.5 to 5 mg appears to be effective in most cases, [7] [8] [9] though a total of 10 mg may be used for local infiltration. Phentolamine 5 mg can be mixed with 5 to 10 mL of either normal saline or lidocaine. The small volume of the distal pulp space may limit the infiltration dose volume to 0.5 to 1.5 mL in the fingertip. Larger volumes and dosages can be used in proximal infiltrations. For intra-arterial infusion at the radial artery in the wrist or the dorsalis pedis on the dorsum of the foot, dosages of 1.5 to 5 mg of phentolamine are suitable. Slow infusion or graded dosages of 1 mg may provide enough phentolamine to reverse ischemia without excessive systemic effects, primarily hypotension.

### Hematoma

Hematoma formation may result from arterial puncture, particularly during axillary and femoral blocks. Direct pressure for 5 to 10 minutes usually controls further bleeding. Use of the recommended 23- to 27-ga needle minimizes bleeding from the punctured artery.

### Infection

Infection is rare and can be minimized by following aseptic technique and using the lowest possible concentration of epinephrine. Injection should be made through noninfected skin that has been antiseptically prepared. Injection through a site of infection may spread the infection to adjacent tissues, fascial planes, and joints. This is particularly a concern in the hand and foot.

### Limb Injury

Injury to the anesthetized limb can result if the patient is permitted to use the limb or is advised to use heat or cold application or to perform wound care before the anesthesia has worn off. With major nerve blocks, the patient should not be released home until sensation and function have returned. With minor blocks, the patient may be sent home but should be properly cautioned. Care must be taken to avoid ischemia-producing compression dressings (e.g., elastic bandages), because the anesthetized area may not sense impending problems.

## SPECIFIC NERVE BLOCKS

### Intercostal Nerve Block

The blocking of the intercostal nerves produces anesthesia over an area of their cutaneous distribution (Fig. 32-1) (Figure Not Available) . It is useful for analgesia of rib fractures. Rib fractures are typically quite painful, causing the patient to splint

respirations to avoid excessive movement of the injured site. The resulting hypoventilation, atelectasis, and poor expectoration may cause hypoxia or lead to pneumonia, particularly in patients with preexisting pulmonary disease and minimal respiratory reserve, in which further impairment of function causes significant respiratory compromise. Anesthetizing the injured rib eases the pain and facilitates deep breathing and coughing.

**Figure 32-1** (Figure Not Available) Area of anesthesia and cutaneous distribution of the intercostal nerve. *(From Moore DC: Regional Block: A Handbook for Use in the Clinical Practice of Medicine and Surgery. 4th ed. Springfield, Ill, Charles C Thomas, 1971, p 159. Reproduced with permission.)*

It is unclear whether intercostal nerve blocks are superior to oral analgesics in the treatment of rib fractures. Current studies suggest that intercostal block may be superior to analgesics in patients who have undergone thoracotomies. [10] [11] Those receiving intercostal nerve blocks had better results on pulmonary function tests, greater oxygenation, and earlier ambulation and discharge than those receiving opioid analgesics. There are no controlled studies comparing intercostal blocks with oral analgesics in patients with the kinds of rib fractures that are commonly managed on an outpatient basis.

There are several arguments against the routine use of intercostal nerve blocks in the emergency department. Rib fractures are often tolerated well in young patients, who usually require minimal oral analgesics. Furthermore, these blocks have a short duration of action. The typical duration of action of a long-acting anesthetic with epinephrine is 8 to 12 hours. However, the patient often receives partial analgesia for up to 3 days, a period of time that cannot be attributed to the direct action of the anesthetic on the nerve. Perhaps the anesthesia reduces muscle spasm and the associated cycle of pain.

The perceived high incidence of pneumothorax and unsuccessful blocks is another reason intercostal nerve blocks are not used in the emergency department. Yet these fears appear to be unfounded. Moore reported that in more than 10,000 individual rib blocks done by physicians in all stages of training, the incidence of pneumothorax was less than 0.1% 12 and Moore and Bridenbaugh reported a 98% success rate in a series of 5000 intercostal nerve blocks. [13] Only 31% of emergency clinicians use this block, suggesting it may be underused. [1]

The suggested approach to discussing intercostal blocks is to give patients the facts with regard to duration of analgesia and possible complications and then allow them to decide on the method for themselves. Often they prefer oral analgesics initially but may return for further relief of pain, at which time they are more amenable to the nerve block.

**Anatomy**

Each thoracic nerve exits the spine through the intervertebral foramen, which lies midway between adjacent ribs. It immediately gives off the posterior cutaneous branch, which supplies the skin and muscles of the paraspinal area. The intercostal nerve continues and gives off the lateral cutaneous branches at the midaxillary line. These

branches are the sensory supply to the anterior and posterior lateral chest wall.

The intercostal nerve runs with the vein and artery in the subcostal groove (Fig. 32-2) (Figure Not Available) . Posteriorly, the nerve is separated from the pleura and the lungs by the thin intercostal fascia. Particular care must be taken to avoid puncture of the thin fascia and underlying lung when blocking the nerve in the posterior aspect of the back. Fortunately, most rib fractures occur in the anterior or lateral portion of the ribs and can be blocked in the posterior axillary line, where the internal intercostal muscle lies between the nerve and the lung's pleura and provides a buffer for minor errors in needle placement.

**Technique**

For adequate analgesia of most rib fractures, the lateral cutaneous branch needs to be anesthetized. Blocks are usually performed between the posterior axillary and midaxillary line at a point proximal to the origin of this branch. Explanation of the procedure, its benefits, and its risks, including potential pneumothorax, systemic toxicity, and ineffective block, should be done before proceeding.

A 10-mL syringe with a 3.75-cm, 23- to 25-ga needle is used. The rib is palpated, and the area is prepared in the usual aseptic manner. The index finger of the nondominant hand is used to retract the skin at the lower edge of the rib cephalad and up over the rib (Fig. 32-3) (Figure Not Available) . With the syringe in the opposite hand, the skin is punctured at the tip of the finger that is retracting the skin. The syringe is held at an 80° angle with the needle pointing cephalad. The hand holding the syringe rests on the chest wall for stability. In this position, the depth of needle penetration is well controlled. The needle is slowly advanced until it comes to rest on the lower border of the rib.

At this point, the skin retraction is released. The skin returning to its natural position moves the needle shaft perpendicular to the chest wall and the needle tip to the inferior margin of the rib. The syringe is shifted from the dominant hand to the index and thumb of the nondominant hand. The middle finger of the same hand rests against the shaft of the needle and, by exerting gentle pressure on the shaft, walks the needle off the lower edge of the rib. Again, the palm of the hand is planted firmly on the chest wall to ensure control of the needle. With the help of the dominant hand, the needle is slowly advanced 3 mm. The needle is aspirated, and then 2 to 5 mL of anesthetic are injected while the needle is carefully moved in and out 1 mm, which ensures that the compartment containing the nerve between the internal and external intercostal muscles is penetrated. This may also serve to minimize intravascular injections. The procedure is repeated ideally on the *2 ribs above and below* to ensure that the overlapping innervation from adjacent nerves is blocked.

Although the procedure just discussed seems extensive, it takes 1 to 2 minutes to perform once the operator is familiar with the technique, and 3 to 5 intercostals can be blocked in 10 minutes total time.

**Precautions**

The needle must be initially placed at the lower edge of the rib. If it contacts the rib above this point, it cannot be walked off the lower edge of the rib at the proper angle. If it is inserted too low, over the intercostal space, it may be advanced too deep through the pleura and into the lung before the operator realizes the misplacement. Before inserting the needle, the depth of the bone should be estimated. If the bone is not encountered by this depth, needle position should be reevaluated. Even after the needle has been properly walked off the edge of the rib, care must be taken to avoid puncture of the pleura and lung. The depth of the intercostal groove in which the nerve runs is 0.6 cm posteriorly, diminishing to 0.4 cm anteriorly.

Because the incidence of pneumothorax is low, a chest radiograph is not routinely required after this procedure. The asymptomatic patient is observed for 15 to 30 minutes and instructed to return if problems arise. If the patient has

**Figure 32-3** (Figure Not Available) Method of retracting skin and the proper needle insertion site for intercostal block. See text for details. *(From Moore DC: Regional Block: A Handbook for Use in the Clinical Practice of Medicine and Surgery. 4th ed. Springfield, Ill, Charles C Thomas, 1971, p 153. Reproduced with permission.)*

symptoms of pneumothorax (e.g., cough, a change in the nature of the pleuritic pain, or shortness of breath), he or she should have a chest film taken before discharge.

If the physician inadvertently causes a pneumothorax, treatment depends on the size. Many pneumothoraces are small. Those <20% may be observed for 6 hours. [13] If the pneumothorax does not grow in size, the patient may be released home with arrangements for follow-up. Needle aspiration of larger pneumothoraces may be all that is needed. A chest tube is necessary if this method fails (see Chapters 8 and 9) .

Toxicity from the epinephrine or the anesthetic is another complication. The intercostal block is associated with the highest plasma concentrations of anesthetic for a given dose when different sites are compared. [14] The exact reason for the high plasma levels is not entirely clear. Moore and colleagues suggest this is because the anesthetic is injected close to the intercostal vessels [14] ; however, other blocks are also performed close to large vessels without a comparable rise in plasma levels. Regardless, the maximum recommended dose of anesthetic should not be exceeded. Systemic absorption of epinephrine may prove dangerous in patients taking monoamine oxidase inhibitors or those with preexisting heart disease of hypertension. Bupivacaine without epinephrine should be used in these patients.

## Nerve Blocks of the Upper Extremity

The upper extremity is supplied by the brachial plexus, whose branches--primarily the median, radial, ulnar, and musculocutaneous nerves--can be blocked at the axilla, elbow, wrist, hand, or fingers. Nerve blocks at the axilla and elbow are seldom used in the emergency department. Nerve blocks of the wrist are performed occasionally before

painful procedures or for repair of injuries to the hand. Metacarpal and digital blocks are used frequently to treat fractures, lacerations, and infections of the fingers.

**Nerve Blocks at the Elbow**

The median, ulnar, and radial nerves can be blocked at the elbow, providing anesthesia to the distal forearm and hand (Fig. 32-4) (Figure Not Available) . These nerves are blocked individually to supplement incomplete axillary blocks or blocked together to provide anesthesia to the forearm and hand. For most injuries extensive enough to require nerve block at the elbow, all 3 nerves must be blocked for successful anesthesia because of the variable and overlapping innervation of the forearm. Furthermore, injuries to the proximal and middle forearm may require an additional circumferential subcutaneous (SQ) field block of the lateral, medial, and posterior cutaneous nerves.

**Ulnar nerve: Anatomy and technique.**

The ulnar nerve can be palpated in the ulnar groove on the posteromedial aspect of the elbow between the olecranon and medial condyle of the humerus (Figs. 32-5 (Figure Not Available) and 32-6) (Figure Not Available) . This nerve supplies the innervation to the small finger and ulnar half of the ring finger and the ulnar aspect of the hand (see Fig. 32-4) (Figure Not Available) .

With the elbow flexed, the nerve is palpated in the groove. A 3.75-cm, 23- to 25-ga needle is inserted 1 to 2 cm proximal to the groove and directed toward the groove parallel to the course of the nerve. The needle tip comes to rest close to the proximal end of the groove. Care is taken to avoid blocking the nerve in the groove, where it is prone to damage. For similar reasons, paresthesia may be elicited but is not vigorously sought. Once the needle tip is properly positioned, 5 to 10 mL of anesthetic are deposited. If a nerve stimulator is used, flexion of the small and ring fingers signals proximity to the nerve.

**Radial nerve: Anatomy and technique.**

The radial nerve and sensory branch of the musculocutaneous nerve run together in the sulcus between the biceps and the brachioradialis muscle on the anterolateral aspect of the elbow (Fig. 32-7) (Figure Not Available) . The block produces anesthesia to the lateral dorsum of the hand and the lateral aspect of the forearm (see Fig. 32-4) (Figure Not Available) .

The sulcus in which the nerve runs is palpated between the sharp border of the biceps muscle and the medial border of the brachioradialis in the antecubital fossa just proximal to the skin crease of the elbow. Palpation is greatly facilitated by having the patient, with the elbow flexed at 90°, contract and relax these muscles isometrically so that their borders are better defined. The skin is punctured with a 3.75-cm, 23- to 25-ga needle halfway between the muscles, or 1 cm lateral to the biceps tendon, at a point 1 cm proximal to the antecubital crease. A paresthesia is sought at a depth of 2 cm by probing in a fan-like pattern. If one is unsuccessful after a brief search, 5 to 15 mL of

anesthetic should be injected at this depth. Because of the depth and poor landmarks of this nerve, the nerve stimulator greatly facilitates the search for the nerve, which, when stimulated, produces extension of the fingers and wrist.

**Median nerve: Anatomy and technique.**

The median nerve runs medial to the brachial artery in the anteromedial aspect of the elbow (see Fig. 32-7) (Figure Not Available) . The nerve block anesthetizes the index, middle, and radial portion of the ring fingers and the palmar aspect of the thumb and lateral palm (see Fig. 32-4) (Figure Not Available) .

The brachial artery is palpated in the flexed arm at the elbow just proximal to the antecubital crease and medial to the prominent biceps tendon. Once the anatomy is defined and marked in the flexed arm, the arm is extended to 30°. A 3.75-cm, 23- to 25-ga needle is inserted slightly medial to the artery and perpendicular to the skin to the depth of the artery, about 2 to 3 cm, and 5 to 15 mL of anesthetic are injected. Again, the nerve stimulator facilitates the process and produces flexion of the wrist and index finger.

## Nerve Blocks at the Wrist

The median, ulnar, and radial nerves may be blocked at the wrist, providing anesthesia to the hand. Although 43% of surveyed emergency physicians use this block in their practice, 89% of these stated that they use it rarely. [1]

Most extensive injuries and procedures for which a wrist nerve block could be used can also be managed using local infiltration or a digital block. Compared with direct infiltration, wrist block anesthesia can have a slow and unreliable onset and can require more time to take effect if all 3 nerves are to be blocked. There are several circumstances, however, in which wrist nerve blocks are more advantageous than other types.

Diffuse lesions that can be difficult to anesthetize with local infiltration can easily be anesthetized with a wrist block. Deep abrasions with embedded debris, commonly the result of "road burn" from bike and motorcycle crashes, can be cleaned and debrided painlessly after a nerve block at the

**Figure 32-4** (Figure Not Available) Cutaneous nerve supply of the upper limb. *(From Bridenbaugh LD: The upper extremity: Somatic blockade. In Cousins M, Bridenbaugh PO (eds): Neural Blockade in Clinical Anesthesia and Management of Pain. 2nd ed. Philadelphia, JB Lippincott, 1988, p 412. Reproduced with permission.)*

wrist. Hydrofluoric acid burns, which require treatment with numerous SQ injections of calcium gluconate, are handled mercifully after a wrist nerve block. Hence, wrist blocks are advantageous in the severely swollen and contused hand, whenever small amounts of anesthetic injected locally may increase the tissue pressure and produce further pain.

Compared with nerves in the axilla and elbow, the nerves in the wrist are more easily located anatomically and can be blocked more reliably. All 3 nerves lie in the volar aspect of the wrist near easily palpated tendons. A nerve stimulator is not necessary but may be useful in locating the nerves, particularly when one is learning how to perform these blocks.

The anatomy and technique for blocking each nerve individually follow. Note that the median nerve lies in the midline and deep to the fascia, and the ulnar and radial nerves lie on their respective sides and have branches that wrap around dorsally. Blocking all 3 nerves at the wrist requires a block that, when viewed end-on, roughly resembles a horseshoe straddling a horseshoe stake (Fig. 32-8) (Figure Not Available) .

**Median nerve: Anatomy and technique.**

In the wrist, the median nerve lies below the palmaris longus or slightly radial to it between the palmaris and the flexor carpi radialis (see Figs. 32-8 (Figure Not Available) and 32-9) (Figure Not Available) . Both tendons are easily palpated, but the palmaris may be absent in up to 20% of patients, in which case the nerve is found about 1 cm in the ulnar direction from the flexor carpi radialis. The nerve lies deep to the fascia of the flexor retinaculum at a depth of 1 cm or less.

The palmaris longus is located by having the patient oppose the thumb and small finger with the wrist flexed against resistance. The site of the nerve block is selected on the radial border of the palmaris tendon just proximal to the proximal wrist crease. A 3.75-cm, 25-ga needle is inserted perpendicularly and advanced slowly until a slight "pop" is felt as the needle penetrates the retinaculum and a paresthesia is produced. If no paresthesia ensues, it may be elicited in a more ulnar direction under the palmaris tendon. If a paresthesia is still not elicited, 3 to 5 mL of anesthetic are deposited in the proximity of the nerve at a depth of 1 cm under the tendon. It is better to err slightly on the deep side of the retinaculum and continue depositing anesthetic as the needle is withdrawn, because the retinaculum is an effective barrier to a successful nerve block from a superficially injected anesthetic.

**Radial nerve: Anatomy and technique.**

The radial nerve follows the radial artery into the wrist but gives off branches proximal to the wrist. These branches wrap around the wrist and fan out to supply the dorsal radial aspect of the hand (Fig. 32-10) .

Nerve block requires an injection in close proximity to the artery and a field block that extends around the dorsal aspect of the wrist. A 3.75-cm, 25-ga needle is inserted immediately lateral to the palpable artery at the level of the proximal palmar crease. At the depth of the artery 2 to 5 mL of anesthetic are injected. Another 5 to 10 mL are distributed in an SQ field block from the initial point of injection to the dorsal midline. The needle must be withdrawn and repositioned to complete the block. The discomfort of numerous needle sticks is decreased if the needle is repositioned to a site that has been

anesthetized previously.

**Ulnar nerve: Anatomy and technique.**

The ulnar nerve follows the ulnar artery into the wrist, where they both lie deep to the flexor carpi ulnaris (see Figs. 32-8 (Figure Not Available) and 32-9) (Figure Not Available) . The flexor carpi ulnaris tendon is easily palpated just proximal to the prominent pisiform bone by having the patient flex the wrist against resistance. At the level of the proximal palmar crease, the artery and the nerve lie just off the radial border of the flexor carpi ulnaris; however, the nerve lies between the tendon and the artery and deep to the artery, making it difficult to approach the nerve from the volar aspect of the wrist without involving the artery.

Nerve block of the ulnar nerve can be carried out by 2 different approaches: lateral and volar (see Fig. 32-9) (Figure Not Available) ; the lateral approach may be easier because of the reason stated previously. For the lateral approach, a 3.75-cm, 25-ga needle is inserted on the ulnar aspect of the tendon at the proximal palmar crease and is directed horizontally under the flexor carpi ulnaris for a distance of 1.0 to 1.5 cm. After a paresthesia is elicited, 3 to 5 mL of anesthetic are deposited. It is important to elicit a paresthesia, because the nerve lies in a thick neurovascular bundle. If no paresthesia is elicited, the needle can be directed toward the ulnar bone at a point deep to the flexor carpi ulnaris, and the anesthetic can be inserted as the needle is withdrawn.

Like the radial nerve, cutaneous nerves branch off the ulnar nerve, wrap around the wrist, and supply the dorsum of the hand. These are blocked with a 5- to 10-mL SQ band of anesthetic from the lateral border of the flexor carpi ulnaris to the dorsal midline (see Fig. 32-8) (Figure Not Available) . Another advantage of the lateral approach is that the dorsal branches can be blocked from the same injection site.

**Nerve Blocks of the Digits**

The digital nerve block is one of the most useful and most used blocks in the emergency department. Indications for choosing it include repair of finger lacerations and amputations, reduction of fractures and dislocations, drainage of infections, removal of fingernails, and relief of pain (e.g., from a fracture or burn). Most emergency physicians (99%) use this block in their practice; 82% use it frequently. [1]

The digital block is superior to local infiltration in most circumstances. Wound infiltration may be a problem in the finger that has tight skin and can accept only a limited volume of anesthetic. Administration of anesthetic into this restricted space increases the tissue pressure, impairing capillary blood flow and causing pain. Fibrous septa in the fingertip also restrict the space available for the injected substance and even limit the spread of small amounts of anesthetic.

**Anatomy.**

Each finger is supplied by 2 sets of nerves. These nerves, the dorsal and palmar digital

nerves, run alongside the phalanx at the 2 and 10 o'clock positions and the 4 and 8 o'clock positions, respectively (Fig. 32-11 (Figure Not Available) *A-D*). Many physicians mistakenly believe that all 4 nerves must always be blocked to obtain adequate anesthesia.

The principal nerves supplying the finger are the palmar digital nerves, also called the *common digital nerves*. These nerves originate from the deep volar branches of the ulnar and median nerves, where they branch in the wrist. The palmar digital nerves follow the artery along the volar lateral aspects of the bone, one on each side, and supply sensation to the volar skin and interphalangeal joints of all 5 digits. In the middle 3 fingers, these nerves also supply the dorsal distal aspect of the finger, including the fingertip and nailbed. Only the volar branches must be blocked to obtain

**Figure 32-10** Distribution, anatomy, and blockade of the radial nerve at the wrist.

adequate anesthesia of these fingers distal to the distal interphalangeal joint.

The dorsal digital nerves originate from the radial and ulnar nerves, which wrap around to the dorsum of the hand. *They supply the nailbeds of the thumb and small finger and the dorsal aspect of all 5 digits up to the distal interphalangeal joints*. Unlike the middle 3 fingers, all 4 nerves are usually blocked in the thumb and fifth finger, especially to obtain anesthesia of the fingertip and nailbed (Fig. 32-12 (Figure Not Available) *A* and *B*).

**Technique.**

The digital nerves can be blocked anywhere in their course, including sites in the finger, in the web space between the fingers, and between the metacarpals in the hand. There are a variety of approaches to the nerves, including the dorsal and palmar approaches and the web space approach. Each has its merits. The technique is similar at each level.

The dorsal approach has the advantage of thinner, less pain-sensitive skin compared with volar approaches. The hand can be held firmly and flat on the table, preventing withdrawal. The disadvantage is that 2 injections are needed from this approach to block both volar digital nerves.

The dorsal approach can be used in the dorsum of the hand at the metacarpals, just proximal to the finger webs at the proximal end of the proximal phalanx, or distal to the web. Clinical situations may dictate which site to use; however, given equal circumstances, the preferred site is just proximal to the finger web. Here the nerve's location is more consistent than in the hand, and there is more soft tissue space to accommodate the volume of injected substance than there is in the distal finger. Digital block at the web is more efficacious in onset and requires less time to anesthesia than metacarpal block done proximal to the metacarpophalangeal joint. [15]

Digital block requires only aseptic injection technique after the skin is prepared with

alcohol or povidone-iodine. Sterile gloves and drapes are not necessary, although examination gloves are recommended.

Anesthesia is deposited at the positions of the 4 digital nerves (2, 4, 8, and 10 o'clock in relationship to the bone), using a 3.75-cm, 25- or 27-ga needle (see Fig. 32-11 (Figure Not Available) *A*). The block is performed from the dorsal surface, where the skin is thinner, easier to penetrate, and less sensitive than that of the volar surface. The needle insertion site is at the web space, just distal to the knuckle at the lateral edge of the bone (Fig. 32-12 (Figure Not Available) *C*). Once the needle tip is subdermal, it usually contacts the bone. A wheal of 0.5 to 1.0 mL of anesthetic without epinephrine is injected at this level. This serves to block the dorsal digital nerve and provide anesthesia at the injection site. The needle is then passed lateral to the bone and toward the palmar surface until the palmar skin starts to tent slightly. The needle is withdrawn 1 mm and aspirated for checking for an inadvertent IV position, and 0.5 to 1.5 mL of anesthetic are injected. This procedure is repeated on the opposite side of the finger. The result is a circumferential band of anesthesia at the base of the finger. *Firm massage of the injected area* for 15 to 30 seconds enhances diffusion of the anesthetic through the tissue to the nerves.

A variation of the dorsal approach is performed as follows: after injecting 1 side of the finger, the needle is redirected (without removing it) across the top of the digit to anesthetize the skin on the opposite side (Fig. 32-12 (Figure Not Available) *D*). The needle is then withdrawn and inserted at the site that was anesthetized, and the block is continued as described earlier. The presumed advantage of this method is that it minimizes the pain of the second skin puncture. This procedure requires that the needle be placed across the dorsal aspect of the finger, allowing the possible disadvantage of extensor tendon puncture and trauma.

The *palmar* and *web space* approaches can be used most successfully for the middle 3 fingers where a single puncture is required to block both volar nerves. This technique takes advantage of the anatomic fact that only the volar digital nerves must be blocked to obtain anesthesia of the total finger (except the proximal dorsal surface). If the thumb or fifth finger must be anesthetized, the dorsal branches must also be blocked to obtain anesthesia of the fingertip and fingernail area.

The palmar approach requires an injection in the palm, which is slightly more painful than an injection in the dorsal skin. The needle is inserted directly over the center of the metacarpal head, and anesthetic is slowly injected while the needle is advanced to the bone. At this point the needle is withdrawn 3 to 4 mm and angled slightly to the left and right of center to block both digital nerves without withdrawing the needle (Figs. 32-13 and 32-14) . To be successful, a palpable soft tissue fullness should be appreciated. The technique requires 4 to 5 mL of anesthetic.

A variation of this is particularly useful in fingertip injuries in toddlers. The finger is pinched side-to-side just distal to the proximal finger crease. This tents the skin at the finger crease, which is injected subcutaneously with 0.5 to 1.0 mL of anesthetic. This single injection diffuses to the volar nerves and provides anesthesia to many fingertip injuries common in toddlers. With the web space approach, the patient's hand is held by

the physician in such a way that the physician's thumb and index finger are over the dorsal and volar metacarpal head, respectively. The physician's third finger is used to separate the patient's fingers to expose the web space, while the fourth and fifth fingers support the finger being anesthetized (Fig. 32-15) . The needle is inserted into the web space, 1 mL of anesthetic is injected, and the needle is slowly advanced until it is next to the lateral volar surface of the metacarpal head. Only 2 mL of anesthetic are injected, and the needle is advanced slowly past the midline of the metacarpal head to the opposite digital nerve (Fig. 32-16) . The operator's index finger is used to palpate a fullness as the anesthetic is injected. By redirecting the needle to the adjacent finger without withdrawing it, both fingers may be blocked with a single puncture.

The anesthetic solution should be 2 to 4 mL of anesthetic *without epinephrine*. The total amount is reduced if the block is performed in the finger itself. The injection should go in smoothly, without resistance of the syringe plunger. Although the finger is forgiving of transient pressure from excessive anesthetic, if the injection site becomes excessively tense as the volume is injected, the amount injected should be limited. If epinephrine-containing solutions are inadvertently used for a digital block of the digits in otherwise healthy individuals without peripheral vascular disease, it is unlikely that serious ischemic injury will occur. Significant vasoconstriction will not last >60 minutes, within the time interval for which an ischemic tourniquet can safely be used in the same area. [16] However, if the entire digit remains blanched for >15 minutes, it is prudent to reverse the alpha-agonism of epinephrine with phentolamine (see Complications and Precautions subsection and Chapter 31) .

Onset of anesthesia occurs in 1 to 15 minutes and lasts for 20 minutes to 6 hours, depending on the anesthetic agent used.

**Alternative techniques**

**Jet injection technique.**

Jet injection for digital nerve block can be used effectively and is less painful than standard needle techniques. [17] The technique described by Ellis uses 0.15 mL of 1% lidocaine delivered by a jet injector at 2600 psi. Three injections are given to the lateral aspect of the proximal phalanx: the first, midway between the volar and dorsal surfaces; the second, dorsal to this; the third, volar. A total of 0.45 mL is administered to each side of the phalanx at the 2, 3, and 4 o'clock positions and the 8, 9, and 10 o'clock positions in relationship to the bone.

The potential disadvantages of jet injection include lacerations that may occur with tangential injection. Holding the injector perpendicular to the skin avoids this problem. Thick skin associated with older age, manual labor, and male gender may require larger volumes of anesthetic.

The advantages of this technique are less pain of injection and avoidance of "needle phobia," particularly in children.

**Transthecal digital block technique.**

The transthecal block is performed by a single injection into the flexor tendon sheath, which produces rapid and complete finger anesthesia. It was first described by Chiu in 1990 after noting rapid finger anesthesia after injection treatment of a trigger finger. [18] Cadaver studies suggest that injected fluid diffuses out of the tendon sheath and around the phalanx and all 4 digital nerves.

The flexor tendon is palpated in the palm proximal to the metacarpal phalangeal joint. A 25-ga needle is introduced at a 45° angle and advanced to the sheath/tendon. Slight pressure is applied to the syringe plunger. If the sheath has been entered, the anesthetic should flow freely. If it does not, it is presumed that the tendon has been entered, and the syringe is withdrawn slowly while constantly applying slight pressure. A total of 2 mL of 1% lidocaine is injected. Smaller volumes are used in children. After the needle is removed, pressure is applied over the tendon proximally to facilitate distal spread. Average onset of anesthesia is 3 minutes. [19]

The advantage of this technique is the single injection. However, Hill and colleagues found the technique to be "clinically equal" to traditional digital blocks. [20] Indeed, they found that patients judged the technique to be slightly more painful and it took slightly longer than the traditional method. Theoretically, the technique may increase the risk of injury to the tendon.

**Complications and precautions.**

The small size of the digital arteries and nerves makes intravascular or intraneural injection less likely. Inadvertent intravascular injection may cause digit ischemia from vasospasm or displacement of blood out of the capillary bed by the anesthetic. Blanching of the finger as the anesthetic is injected suggests intravascular

**Figure 32-17** (Figure Not Available) Cutaneous distribution of the nerves to the lower extremity. *(From Bridenbaugh PO: The lower extremity: Somatic blockade. In Cousins M, Bridenbaugh PO (eds): Neural Blockade in Clinical Anesthesia and Management of Pain. 2nd ed. Philadelphia, JB Lippincott, 1988, p 425. Reproduced with permission.)*

injection. If this is observed, the injection should be discontinued. Usually the ischemia is transient and self-resolving, and serious complications are rare. Massage or topical application of nitroglycerin paste may be attempted if ischemia persists. Vasoconstrictors such as epinephrine are best avoided when blocking the digital nerves. Although the incidence of vasospasm and resultant ischemia is rare and primarily occurs in patients with underlying vascular disease, [21] this complication is easily avoided by the choice of anesthetic agent. As noted above, if one mistakenly chooses an epinephrine-containing solution and vasospasm develops, the ischemia should be relieved with local infiltration of phentolamine (see Chapter 31) .

Commonly the digital nerve is lacerated or damaged by the initial injury to the finger. Careful evaluation using 2-point discrimination should be performed to determine the

extent of nerve injury before nerve block. Even if nerve injury is questionable, it should be documented in the chart, and the *patient should be advised of the injury before the nerve block.* Careful evaluation and patient education should prevent misconceptions as to the cause of the nerve injury. Although most isolated digital nerve injuries are not debilitating, they heal slowly and can be annoying to the patient. Digital nerve injury proximal to the distal interphalangeal joint may be repaired surgically. Nerve repair may be immediate when specialty consultation is available or delayed following initial simple closure.

## Nerve Blocks of the Lower Extremity

The lower extremity is supplied by 5 nerves whose branches can be blocked at the hip, knee, ankle, foot, or toes. As in the arm, proximal nerve blocks in the leg are seldom used in the emergency department. Nerve blocks at the ankle are used occasionally in the treatment of foot lacerations and to perform otherwise painful procedures on the foot. Metatarsal and digital blocks in the foot are used frequently to treat ingrown toenails, fractures, and lacerations of the forefoot and toes.

### Nerve Blocks of the Hip

Nerve blocks of the femoral, obturator, lateral femoral cutaneous, posterior cutaneous, and sciatic nerves at the hip provide anesthesia and paralysis to the skin and muscles of the leg (Fig. 32-17) (Figure Not Available) . Posteriorly, the posterior cutaneous and sciatic nerves can be blocked together with a single injection. Anteriorly, the femoral, obturator, and lateral femoral cutaneous nerves can be blocked by 3 separate injections or by a single injection using the 3-in-1 technique described by Winnie and colleagues. In this technique a large amount of anesthetic is injected into the femoral nerve sheath and permitted to track into the pelvis to the point at which the anterior nerves run in a common sheath. [22]

Proximal lower extremity nerve blocks are rarely used in the emergency department. Injuries to the thigh and calf that call for extensive repair and anesthesia often require a specialist and repair in the operating room. Injuries to the ankle and foot are more easily anesthetized at that level. Only 3% of emergency physicians use blocks at the hip on occasion. [1]

Femoral nerve blocks alone may be the analgesia of choice for femoral shaft fractures. Studies supporting the femoral block in the treatment of femoral shaft fractures date back to 1940 and continue to appear. [23] [24] [25] In a study by McGlone and colleagues, patients preferred femoral block to opioid analgesia; however, this means of analgesia has yet to be adopted as routine treatment for femoral shaft fractures. [24] The procedure requires only femoral nerve blockade and does not rely on the performance of a successful 3-in-1 block.
